Tor-Periphery Insider Networks*

September 2025

Abstract

How do insiders respond to regulatory oversight on the use of insider information? History suggests that they form more sophisticated networks to circumvent regulation. We develop a theory of the formation and regulation of insider information networks. We show that agents with sufficiently complex networks bypass any given regulatory environment. In response, regulators employ broad regulatory boundaries to combat gaming. Tighter regulation induces agents to migrate activity from existing social networks to a *tor-periphery network*, a novel core-periphery network topology with a layered core of agents specialized in specific roles along transmission chains. A small group of agents endogenously arise as intermediaries for the bulk of transmissions.

1 Introduction

From 1928 to 1932, Albert H. Wiggin, then president of the Chase National Bank, accumulated over $10,000,000 solely by trading Chase stock. $4,000,000 was made in the Crash of 1929, during which the stock market crashed, and with it, Chase as well. Wiggin had been shorting his own bank. Wiggin's trades were as legal as much as they were met with public outrage. In an effort to restore confidence in market integrity, the Securities Exchange Act of 1934 was passed which birthed the Securities Exchange Commission (SEC). Section 16 of the act, also known as the "anti-Wiggin" proposal, was specifically included to root out abusive securities trading by people with insider information.[1]

In 2008, Mathew Martoma, portfolio manager at hedge fund SAC Capital Advisors, made a twenty-minute phone call to owner Steven A. Cohen. Within a span of a week, Cohen reversed his long position in pharmaceutical firms Elan and Wyeth by nearly a billion dollars, which ultimately generated a profit of over $270,000,000. Martoma was later convicted of insider trading. Insider information was passed through a long chain of communication – from Elan to a doctor, to Martoma, who was introduced by an expert network firm. Importantly, connections made through information intermediaries, such as expert network firms, differ in nature from those underpinning historical cases of insider trading, which typically trace back to social and professional relationships.[2] The conviction was the culmination of a painstaking six-year investigation by the SEC.[3]

These two instances of insider trading, set apart by nearly a century, draw a striking contrast. In the first case, the insider legally traded directly with his information. In the latter, transmission was achieved through a complex network of connections that had adapted to greater regulatory sophistication. The sender and receiver were otherwise unrelated, with no overlapping social or professional networks, channels through which information typically diffuses. Instead, transmission was facilitated by an intermediary specializing in bringing together sources of information and those who seek it. While regulators have become increasingly sophisticated, so have those that

[2] We formally explore this aspect in Section 5.4.

[3] http://www.newyorker.com/magazine/2014/10/13/empire-edge

are intent on escaping detection (whom we will conveniently refer to as "insiders"). This suggests that in understanding the cat and mouse game between regulators and insiders, a key consideration is the networks that agents form in order to circumvent regulation, and how regulators might cope with agents' tactics.

We develop a model of endogenous network formation to study this dynamic between regulators, who set and enforce the regulatory environment, and agents, who form links to pass material non-public information to others to exploit for trading activity without getting caught. Agents can form costly links that enable them to transmit information. Traders that receive information through a shorter chain are able to generate greater trading profits, but agents may want to transmit through a long chain to circumvent regulation.

The regulator's objective is to detect and punish agents for sharing information, which imposes negative social externalities. In order to punish violations, the regulator must provide direct evidence that a trader suspected of insider trading did in fact obtain information from an insider. That is, the regulator must be able to map the entire path of transmission in order to punish the insiders. The regulator cannot directly observe the network or transmissions between agents , and must incur regulatory costs associated with enforcing insider trading cases that increase with network distance between the insider and the trader.[4]

Our modeling approach to regulatory costs holds literal resemblance to costs borne by regulators and prosecutors to successfully investigate and bring forth an insider trading case. In the pivotal case of *US v. Newman*, the court ruled in favor of defendants because the traders were "three to four levels removed from the [insider]," adding that there had not been a single case in which "tippees as remote as [the defendants were] held criminally liable for insider trading."[5] More generally, regulatory agencies monitor financial markets for unusual or suspicious activities, especially around significant events that lead to predictable market movements. A successful investigation must meet two conditions: first, provide proof that the user of insider information knows it is so, and second, proof that the sender benefitted from sharing the information, in a form of *quid pro quo*. Investigators build a case by working backwards and investigating linked individuals to track down the provenance of in-

[4]In Section 6.1, we also explore legal boundaries arising from the conflict between enforcement and the violation of social liberties and privacy.

[5]See here for more details.

side information. As the distance between an individual and insider increases, more resources must be dedicated to uncover details about the subject's relationships, communications, and behavior offering (circumstantial) evidence of knowledge, as well as some form of mutualization of insider trading profits. This process involves costs associated with obtaining permits and rights to analyze financial transaction records, private communications, and in some instances, even wiretapping. We view our modeling approach to be a direct analog of insider trading regulation. However, we also consider how other forms of costs may affect enforcement.

First, we show that regulatory ambiguity arises as an equilibrium phenomenon. For any given enforcement strategy chosen by the regulator, agents with extensive networks can conceal their transmissions by using longer chains. Agents can game the system. Importantly, increasing the penalty from detection or regulatory search intensity does not generically hinder the use of insider information. This is reminiscent of Tsebelis (1989). As a result, in equilibrium, the regulator mixes between low and high intensities of enforcement, effectively employing regulatory ambiguity. Doing so induces agents to engage in riskier transmission behavior, allowing the regulator to successfully catch the agent with a positive probability.

Our analysis rationalizes a long standing position taken by regulatory institutions that advocate for flexible, broad guidelines on what constitutes insider trading. Regulatory institutions have been criticized for only loosely defining what constitutes illegal activity pertaining to the use of insider information. With broad rules governing insider trading, courts have been relied upon to ultimately determine illegality. We show that a precise regulatory framework necessarily allows for more gaming, as information networks quickly adapt to the regulatory environment.[6]

Second, we show that regulatory ambiguity impacts agents' network formation. In particular, we show that agents value being part of a network that enables flexible transmission of information, or which facilitates multiple paths of varying distance between agents. A flexible network provides agents with the option of transmitting information either through a risky, direct path, or a safer, longer path.

In equilibrium, agents form what we call a *tor-periphery network*, a novel type of core-periphery structure in which the core consists of three distinct layers: sender re-

[6]The need for deliberately imprecise regulation to effectively combat gaming is a sentiment that extends beyond the context of insider trading regulation. For instance, Greenwood et al. (2017) argues that one of the key benefits of bank stress tests is its flexibility. The use of ambiguity arises more generally in other contexts (for example, see Glazer and Rubinstein (2014)).

lays that connect senders to the core, receiver relays that connect the core to receivers, and middle relays that form the connective structure within the core. This network is similar to the structure used by Tor (The Onion Router), a network designed to ensure anonymous communication over the internet. In the case of Tor, distinguishing between sender and receiver relays helps to ensure anonymity among members of the network. For a given message, the sender relay knows the initial sender and the receiver relays knows the final receiver, but no one along the transmission path knows both. In our framework, the tor-periphery structure instead serves to create opacity *vis-à-vis* an outside regulator. It achieves this by facilitating the relay of information over extended paths that are intentionally difficult for a regulator to track, using a minimal number of connections between intermediaries. Indeed, just as an attacker in the Tor network must compromise multiple relays to deanonymize a communication's full path, the regulator in our model must successfully trace information from its origin to its ultimate recipient through this deliberately obfuscated multi-layered structure.

Our theory yields several testable empirical implications. In equilibrium, ambiguous regulatory boundaries induce insiders to share information through both short and long chains, with varying levels of risk of getting caught. Consequently, it predicts that the *observed* set of insider trading cases should involve shorter chains, which are also more profitable. Our characterization of insiders' transmission strategies map closely to those observed in recent insider trading cases. The bulk of observed cases involve shorter chains, supporting a tradeoff insiders face between path length and enforcement risk.[7] In the fewer observed cases involving sophisticated agents, a core of intermediaries were found to "shuffle" insider information through a chain of intermediaries on behalf of corporate insiders and hedge funds, requiring costly (and sometimes failed) prosecution attempts.[8] Furthermore, empirical studies find that trade profitability declines with path length, for example when the trader is at the fourth or fifth link (Ahern, 2017).

Our theory also predicts that the *maximum* regulatory boundary plays a vital part in constraining the profitability of insider trading. Thus, a shock to regulatory costs or other limitations on the regulatory boundary directly benefit insiders, who can

[7]Insider trading cases brought forth by the SEC can be found here.

[8]Analysis on the network of corporate insiders reveals that insiders are tightly connected, and finds evidence for information propagating through long chains within the network (Tamersoy et al., 2013).

more aggressively transmit information by using shorter chains and increase profits. Pierce (2023) examines the performance of traders affected by insider court decisions that exogenously restricted the maximum regulatory boundary.[9] Consistent with our predictions, Pierce (2023) finds significant increases in the stock-picking ability of affected traders following restrictions, for example, around common insider trading events, such as earnings surprise announcements.[10]

We extend our model to consider when agents are endowed with existing social networks. We show that when regulatory enforcement becomes sufficiently strong, agents' information sharing shifts away from their respective social networks and instead prompts the formation of more centralized and complex insider networks. In this context, the model generates an endogenous rise of intermediaries as a reaction to greater regulatory sophistication. Intermediaries in the core are responsible for matching and transmitting information between a large mass of senders and receivers. Moreover, by extending its constituency, the core is able to adjust its flexibility to arbitrarily greater regulatory powers at a negligible cost. This suggests that in an environment where regulation becomes more stringent over time, the flexible core offers a dynamic form of flexibility as well.[11]

Our results imply that strengthened regulatory and legislative initiatives may trigger demand for, and therefore creation of, more sophisticated networks. As agents' typical methods to exploit inside information become too risky, intermediaries naturally arise to facilitate transmission between agents with greater flexibility and reach. In support of this, information intermediaries, such as expert network firms, have been, in the last decade, implicated directly and indirectly in a number of insider trading cases in the United States.[12] These firms are consulting agencies that specialize in connecting clients to experts spanning various sectors and fields. Indeed, legislative and regulatory actions have been claimed to be at least partly responsible for the growth of the expert network industry (Jeng (2013)), which according to some industry estimates, roughly doubled in size (by revenue) from 2012 to 2018. These firms have been found to offer a discrete channel of information transmission and even

[9]We consider a direct analog on how legal boundaries affect insider regulation in Section '6.1.

[10]See also Kacperczyk and Pagnotta (2024), who find similar patterns of changes in trading behavior following shocks to the legal environment.

[11]In the US, enforcement indeed appears to have become stronger over time. For example, see Silvers (2016).

[12]See https://www.sec.gov/spotlight/insidertrading/cases.shtml for details on select cases involving expert networks.

insulate clients from legal trouble by obscuring whether clients know that information constitutes inside information.[13][14]

A resounding takeaway of our theory is the ability for agents to form networks that flexibly adapt to allow for long transmission paths. We extend the model to consider the impact of a whistleblower program, through which the regulator targets the tor to extract intermediate transmissions within the chain.[15] Whistleblowing effectuates voluntary disclosure by intermediaries, thereby shortening the path length required for the regulator to investigate, and enabling enforcements to extend beyond the regulatory boundaries. This has two implications: from an ex-ante standpoint, this forces agents to use longer transmission paths and deters agents from more egregious use of inside information; from an ex-post standpoint, whistleblower programs succeed in unraveling more sophisticated insider trading schemes. Both predictions are empirically corroborated. Consistent with our predictions, Raleigh (2020) documents a deterrent effect of whistleblower programs and shows a drops in profitability of traders affected by whistleblower programs. Although a specific breakdown is not publicly available, the SEC's whistleblower program has recovered over 6 billion dollars relating to securities law violations as of 2022. These bolster arguments that whistleblower programs, despite the hefty bounties offered to whistleblowers, may be complementary to existing investigative tools.

Finally, we explore how agents may achieve optimal transmission in a decentralized manner. We demonstrate that the optimal transmission strategy is implementable using simple rules, which replicate the transmission of insider information through paths of varying distance without any ex-post multilateral communication or coordination. Furthermore, we show that through decentralized transmission, insiders are able to further obfuscate information about the source of the tip, thereby increasing

[13]For example see SEC v. Longoria involving expert network firm, Primary Global Research (PGR). The complaint, which outlines how PGR employees "passed inside information" to clients, explains: "When soliciting consultants for PGR, [the employee] made clear that telephone conversations with PGR clients would not be monitored or recorded."

[14]In the monumental case of SAC Capital, the expert network firm had a compliance program put in place to insider trading, but was circumvented with ease. Per the SEC complaint: "Martoma and Gilman also took steps to conceal the true topic of their conversations from the expert network firm. For example, when Martoma scheduled a consultation with Gilman [...], Martoma reported to the expert network firm that the purpose of the call was 'Follow-up with Dr. Gilman: AAN Abstract Preview' even though [they] had discussed [insider information]."

[15]A similar strategy is also observed against Tor, whereby enforcement agencies target nodes in Tor to deanonymize users. For example, see the NSA's actions against Tor revealed in 2013.

an investigation's burden of proof. When this translates into higher regulatory costs, it has the effect of constricting the regulatory boundary, enabling insiders to reap greater profits in equilibrium.

While our main application is in the context of insider trading networks, we believe that the model's insights apply to a broader set of applications. A pivotal feature of our model is that the regulator must map the path between the sender and the receiver in order to prosecute. Thus, investigative costs scale with number of entities it must surveil in order to unravel the entire path. We emphasize that this property crucially shapes agents' strategies for circumventing regulation. Long chains are essential and, furthermore, a cheap and effective method to increasing the cost incurred by regulators attempting to track transmissions. In this respect, our model is applicable to a broader set of economic problems on the regulation of transmission networks where regulatory actions require a high burden of proof, and also involve investigations that occur at the entity level. One application is money laundering and circumvention of capital controls. Money laundering operations commonly involve "layering" – a practice of transferring through numerous accounts – that obfuscates a fund's source from regulators.[16] The practice of layering is observed in other criminal networks (Jacopo, 2022). Similar challenges arise in the enforcement of capital controls. Notably, leaked documents referred to as the "Panama Papers," revealed an extensive network of off-shore financial intermediaries and shell companies that helped evade regulatory scrutiny dating back to the 1970s.[17] Our model also relates to the design of private transmission networks aiming to prevent external actors from unraveling messages. Our equilibrium network shows strong parallels to the operational design of tor networks, which use multiple intermediate nodes to obfuscate the link between end points of a transmission (Goldschlag et al., 1996; Dingledine et al., 2004).

Beyond economic applications, our paper provides an theoretical foundation for the design of Tor (The Onion Router), which is an overlay network designed for anonymous communication first developed by the United States Naval Research Laboratory (Goldschlag et al., 1996; Reed et al., 1998; Goldschlag et al., 1999). Tor aims to provide users with privacy regarding their identity and internet activity and is associated with criminal activity (McCoy et al., 2008). Although our model originates from an entirely different economic context, the similarities in their objectives translate into

[16]See https://www.fincen.gov/history-anti-money-laundering-laws.
[17]See https://www.icij.org/investigations/panama-papers/.

strong parallels in the tor-periphery network and Tor. As in the tor-periphery network, Tor consists of three distinct types of nodes that relay encrypted messages between a sender and receiver: entry, middle, and exit relays. Tor uses layered relays to be resilient to attacks to de-anonymize web traffic. For example, attackers could run malicious relays to intercept messages within the network. Layered relays ensure that no single relay in the chain is privy to knowledge about the entire path.[18] Thus, Tor limits the level of information leakage from any single relay that is compromised, so that an attacker cannot learn both the identity of the sender and the receiver. In order to learn both the identity of the sender and the contents of communication with certainty[19], an attacker must successfully compromising the entire chain of relays – much like the success conditions of the regulator in our model.[20] In this sense, our model provides an economic rationale for the design of onion routing in a setting of endogenous network formation.[21]

2 Contribution and Related Literature

Our main application is on the regulation of insider trading ((DeMarzo et al., 1998; Acharya and Johnson, 2010)). This paper is the first to our knowledge to theoretically study the formation of insider networks. As in DeMarzo et al. (1998), our paper takes as given the objective of a regulator to detect and deter the sharing of insider information. We complement DeMarzo et al. (1998), which focuses on a regulator's choice of when to conduct an investigation, by studying the joint equilibrium determination of regulation, network formation, and information transmission. Importantly, in our setting, insiders are able to form sufficiently complex networks that allow them

[18] In our model, this feature is implemented through the use of decentralized transmission mechanisms, outlined in Appendix B.

[19] As in our environment, some information can be gleaned from an imperfect attack (Sun et al., 2002).

[20] There are some differences to note. In electronic communication networks, congestion and throughput matter significantly. Given the potential illegality of activity, exit relays, who directly interact with the targeted end-point are subject to greater liability. Third, in contrast to our framework, in which the network is not directly observed, Tor maintains a public directory of relays to make its service accessible to the public. Given the voluntary nature of the relays, it is more susceptible to network infiltrations discussed in Section 6.3.

[21] There is a large literature in computer science that considers the design of privacy-enhanced technologies. Most closely related to ours in spirit is Feigenbaum et al. (2007), which uses an adversarial model to theoretically study the possibilistic anonymity properties of onion routing, and (Feigenbaum et al., 2012), which expands on the anonymity guarantees offered by onion routing in a probabilistic framework.

to circumvent regulation, albeit at a cost. Our theory makes two important departures from DeMarzo et al. (1998). First, DeMarzo et al. (1998) concludes that even if random investigation policy is allowed, a simple non-random enforcement policy is optimal. In our setting, enforcement policy is necessarily ambiguous (i.e. subject to randomness) due to the possibility of gaming by agents, which explains a long-standing policy stance of the SEC and other regulators. Second, regulators in DeMarzo et al. (1998) choose, in equilibrium, to "tolerate" smaller insider trading schemes and investigate those with larger profits, which maximizes its effect on curtailing insider trading volume while economizing on investigation costs. In contrast, in our model, regulation works by making the use of insider information via shorter chains costlier. Insiders face a tradeoff between transmitting through shorter chains, which is more likely to be prosecuted, and longer chains, which are safer but diminish profitability. Our results are consistent with empirical observations that a significant fraction of insider trading cases brought forth by the SEC involve short chains, and also sometimes accrue surprisingly small profits to insiders.

An extensive literature examines the diffusion of information through social networks in financial markets. Cohen et al. (2010) find strong evidence of information diffusion through educational ties. Maggio et al. (2017) find extensive evidence of information diffusion through broker networks. Ahern (2017) shows that a majority of prosecuted insider trading cases involve insider information being transferred through geographical, family, and social networks. An implication of our paper is that as regulatory pressures increase, insider trading activity migrates from existing networks to those that better insulate agents from detection and prosecution.

Our paper is related to the literature on information transmission in endogenous networks. Acemoglu et al. (2014) studies how information aggregation occurs through communication on endogenous social networks. Bloch and Dutta (2009) studies how communication networks with endogenous link strength bring rise to star networks. We make a unique contribution by studying the formation of information networks and its interaction with the regulatory environment.[22] We show that a core-periphery structure arises endogenously in insider networks, and furthermore show that a small number of agents act as intermediaries to facilitate information transmission. Our result also relates to bottlenecks and essential intermediaries which Manea (2018)

[22] A few papers have studied the impact of regulation on networks in other contexts. For example, see Erol and Ordoñez (2017) and Erol (2017).

takes as given.

We are the first, to our knowledge, to show the endogenous formation of tor-periphery networks. Our insights are applicable to other settings where agents value privacy, and can use networks as a strategic tool for the transmission of information or goods in a game against an adversary. Agents committing money laundering may utilize a long chain of financial intermediaries in order to obfuscate the source and destination of money transfers. The model is relevant for studying networks for organized crime or terrorism in which agents form networks to conceal communication and money transfers. Our results are consistent with empirical studies that document the use of long intermediation chains in terrorist networks intended to conceal relationships and preserve secrecy (Krebs (2002)), as well as the emergence of core-periphery structures in transnational criminal networks (Williams (2001)). Finally, our paper contributes broadly to the literature on attack and defense in networks.[23]

3 Baseline Model of Network Formation

We begin by describing the baseline model with a discrete number of agents.

Agents. There are three distinct and finite sets of agents $A = S \cup I \cup R$: senders $s \in S$, receivers $r \in R$, and intermediaries $i \in I$. Senders are insiders who sometimes obtain inside information; receivers are traders with potentially the means to use inside information for profitable trading gains; intermediaries are agents who are able to form links with senders, receivers, and other intermediaries. In the baseline model, given our focus on the interplay between agents and the regulator, we assume that agents A perfectly coordinate and make decisions as a single entity. [24]

Network formation and transmission. In the beginning of the model, A forms *links* $L \subset \{\{a, a'\} : a \in A \text{ and } a' \in I\}$ at cost $c(L)$, which are necessary for information transmission. Links are not observed by the regulator. A link between an intermediary and a non-intermediary costs η, and a link between any two intermediaries costs η'. The total cost $c(L)$ is additive over links. These links are assumed to represent trusted relationships between agents. After links are formed, each sender independently obtains distinct pieces of inside information with probability ζ. Let

[23]For example, see Acemoglu et al. (2016), Dziubiński and Goyal (2017), Hoyer (2012), Haller (2016), and Hoyer and Jaegher (2016).

[24]This is akin to assuming that all costs and profits are shared equally between all agents in A. In Appendix B, we outline protocols that enable agents to transmit information and disseminate profits in a decentralized manner with limited communication and coordination.

this subset of senders be $\tilde{S} \subset S$. Nature also determines a receiver $r_s \in R$ for each $s \in \tilde{S}$, who is able to exploit s's information to implement profitable trading strategies. For example, receivers, such as hedge funds, may each have a proprietary view on the state of play, and the information of the sender completes the specific receiver's information set in a way that translates into a profitable trading strategy.[25]

Hence, gains from inside information arise only if s is able to relay the information to r_s. For each $s \in \tilde{S}$, transmission is feasible along all paths in L that connect s and r_s through intermediaries, where a path for s is denoted $p_s = (s, i_1, i_2, ..., i_{\Delta_s}, r_s)$ and the set of transmission paths across $s \in \tilde{S}$ as p. We call Δ_s, the number of intermediaries between s and r, as the depth (or distance) of path p_s. For each $s \in \tilde{S}$, the sender, in coordination with other agents in A, chooses whether to transmit or not, and if so, the path p_s through which information is transmitted. Upon successful transmission, r_s uses the inside information to generate $\beta(\Delta_s)$ in trading profit, and a social externality cost of $\beta'(\Delta_s)$, where β and β' strictly decrease in Δ_s. We assume that $\beta(\Delta_s) - \beta'(\Delta_s) < 0$ for all Δ_s, such that insider trading is net costly. In Appendix A, we extend the model to allow for insiders to explicitly trade on financial markets.

Regulation and Enforcement. Insider trading imposes a negative social externality. There is a regulator G whose objective is to minimize social costs that arise from the exploitation of inside information. In the event that a receiver r_s trades using inside information, an investigation starts.[26] Investigations operate at the agent level. Since the regulator is not able to directly observe the network, the regulator starts with r_s and searches through r_s's links to identify the provenance of receiver's information. In the beginning of each investigation, the regulator G sets a *regulatory bound* m_s, which determines the *maximum depth* of an investigation, and results in a cost $\kappa(m_s)$, where $\kappa(\underline{m}) = 0$ for some $\underline{m} \geq 1$, and κ is strictly increasing for all $m_s \geq \underline{m}$.[27] For simplicity, we assume that G's action set is restricted to $m_s \geq \underline{m}$.

[25] This relates to the *mosaic theory*, an industry argument that information-based profitable trades require putting together various pieces of information that are each, independently, not sufficient.

[26] Given our focus on the network aspect of regulation, we are assuming for simplicity that the probability of the regulator detecting insider trading is 1. However, results hold generally for imperfect detection. In practice, regulators must dedicate limited investigative resources judiciously and are not expected to investigate all cases with signs of suspicious activity. This problem is the main focus of DeMarzo et al. (1998), which finds that investigations should target trades associated with large volume and/or price movements.

[27] In effect, we also abstract from the decision of whether or not to investigate a trade, since simple investigations are not costly. Several past studies explore this as key component (e.g. DeMarzo et al. (1998)).

With slight abuse of notation, we use sometimes m to denote the set of m_s.

For each investigation, the regulator begins with r_s and explores all their links to identify the agent that shared the information with r_s. Continuing this approach, the regulator recursively tracks the transmission path along p_s, up to a maximum of m_s intermediaries on the path.[28] If $m_s \geq \Delta_s$, an investigation is said to be successful in revealing the entire path of transmission. If investigation succeeds, the regulator imposes a punishment $\gamma(\Delta_s)$ on A, and recovers $\gamma'(\Delta_s)$, where γ, γ' strictly decrease in Δ_s. The punishment is assumed to be sufficiently large so as to have detterent effects, i.e. $\beta(m) - \gamma(m) < 0$ for all m. Illustrative examples of successful and failed investigations are in Figures 1 and 2. In the baseline model, investigation depth m_s encompasses a search that involves exploring target agents and their links along the transmission path. Our approach encompasses a broad set of regulatory cost structures, which we cover in detail in Section 6.

Figure 1: Successful search by the regulator

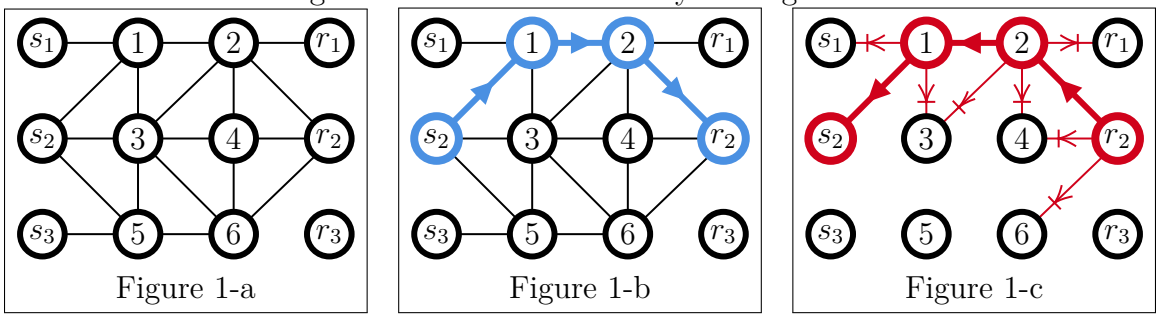

Figure 1-a Figure 1-b Figure 1-c

Figure 1 illustrates the game. The network available is shown in Figure 1-a. There are many paths that the agents can utilize. For example, $s \to 3 \to 4 \to r$ is a path of length 3; $s \to 3 \to 5 \to 6 \to 4 \to 2 \to r$ is a path of length 6. Figure 1-b illustrates the strategy of choosing the path $s \to 1 \to 2 \to r$. Figure 1-c illustrates the strategy of the regulator choosing some $m \geq 3$. Given m, the regulator can hold investigations for m steps until evidence is found. In the first round, r and all of its incoming links are inspected: $2 \to r$, $4 \to r$, and $6 \to r$. Upon the investigation, the regulator finds that the information has been sent by 2. In the second round, the regulator investigates 2 and all of its incoming links, $1 \to 2$, $3 \to 2$, and $4 \to 2$. The regulator discovers that information has been sent by 1. In the third round, the regulator inspects 1 and all of its incoming links: $s \to 1$ and $3 \to r$. The regulator finds definitive evidence that information was transmitted from s to r, and can inflict a punishment.

Timing and payoffs. The game is between A, who forms a network consisting of links L and picks transmission paths p, and the regulator G, who chooses regulatory

[28] Investigations typically triggered when regulators monitoring financial markets detect suspicious trading activity. Hence, we consider investigations that begin with r_s for expositional purposes. Technically, we could also allow for investigations to start with s, or also work from both ends of a path p_s. In either case, it is sufficient that the regulator is able to identify either the r_s or s.

Figure 2: Failed search by the regulator

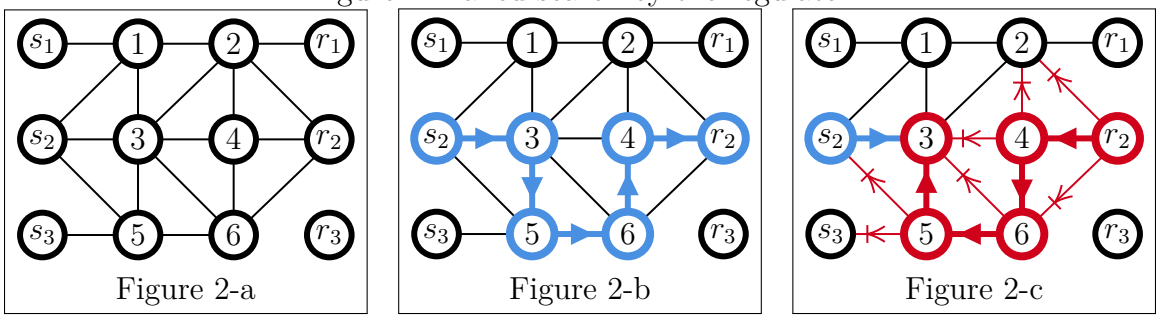

Figure 2-a Figure 2-b Figure 2-c

Figure 2 illustrates the game with failed search. Figure 2-a is the network. Figure 2-b illustrates the transmission strategy employed by the agents: $s \to 3 \to 5 \to 6 \to 4 \to r$. This is a path of length 5. Figure 2-c illustrates the search upon the regulator choosing $m = 4$, the maximum number of rounds for search. First, r and all of its incoming links are inspected: $2 \to r$, $4 \to r$, and $6 \to r$. Upon the investigation, the regulator finds that the information has been sent by 4. Then 4 and all of its incoming links are inspected: $2 \to 4$, $3 \to 4$, and $6 \to 4$. Upon the investigation, the regulator finds that the information has been sent by 6. The search goes on this way. In the last round, upon the inspection of 5 and all of its links $r \to 5$ and $3 \to 5$, the regulator finds that the information has been relayed by 3. However, the search fails to identify the entire transmission path, and insiders are not prosecuted.

bounds m. A and G do not observe each others' actions.[29] Denote $S^* \subset \tilde{S}$ the set of senders whose information A chooses to transmit, and ι_s the indicator for $m_s \geq \Delta_s$. The payoff functions in the corresponding game are

$$V_A(L, p, m) = -c(L) + \mathbb{E}_{\tilde{S}}\Big[\sum_{s \in S^*} \left(\beta(\Delta_s) - \iota_s \gamma(\Delta_s)\right)\Big]$$

$$V_G(L, p, m) = -\sum_{s \in S} \kappa(m_s) + \mathbb{E}_{\tilde{S}}\Big[\sum_{s \in S^*} \left(-\beta'(\Delta_s) + \iota_s \gamma'(\Delta_s)\right)\Big].$$

Notice G's largest possible gain from an investigation that succeeds upon reaching depth m_s is $\gamma'(m_s) - \kappa(m_s)$. This is a strictly decreasing function of m_s and positive at zero. Define

$$\overline{m} = \sup\{m_s \in \mathbb{N} : \gamma'(m_s) - \kappa(m_s) \geq 0\}$$

Note $m_s > \overline{m}$ is strictly dominated by $m_s - 1$ so regulator never uses a depth $m_s > \overline{m}$.

Our focus is Nash equilibria wherein the choice of the network is a pure strategy, which we shortly call *equilibria*. We assume $\overline{m} < \infty$ and $\zeta|S|\beta(\overline{m}+1) - \eta(|S|+|R|) > 0$ so that pure strategy Nash equilibrium networks exist.[30]

[29] Thus the game is strategically equivalent to a simultaneous move game where actions are (L, p) and (m).

[30] A qualitative implication of our setting is that insider trading cannot be fully warded off from financial markets. This insight hinges on the assumption that investigation costs to prove insider trading can grow unboundedly if an investigation continues indefinitely. That is, the cost κ eventually

4 Equilibrium Analysis

4.1 The Virtue of Regulatory Ambiguity

As the network is a pure strategy, we can lay out necessary conditions for regulation and transmission strategies as partial equilibrium properties for a given network. Let the set of paths between s and r_s in L be denoted

$$P(s, r_s, L).$$

We show that the regulator employs a form of regulatory ambiguity in equilibrium:

Theorem 1. ***(Regulatory Ambiguity)*** *Let L be the network, and suppose that $s \in \tilde{S}$. Consider the equilibrium transmission and regulation strategies regarding s. If s and r_s are connected by at least one path of distance at least $\overline{m}+1$ and one path of distance between $\underline{m}+1$ and $\overline{m}$, then the regulator plays a mixed strategy. In particular, the support of G's strategy is*

$$\{\Delta(p) : p \in P(s, r_s, L),\ \underline{m} \leq \Delta(p) \leq \overline{m}\}$$

The distances of paths in the support of A's strategy is

$$\{\Delta(p) : p \in P(s, r_s, L),\ \underline{m}+1 \leq \Delta(p) \leq \overline{m}\} \cup \{\overline{\Delta}(s, r_s, L)\},$$

where $\overline{\Delta}(s, r_s, L) := \min\{\Delta(p) : p \in P(s, r_s, L),\ \overline{m}+1 \leq \Delta(p)\}\}$.

The above theorem formalizes the potential need for the regulator to employ regulatory ambiguity, in the form of a mixed strategy in regulatory bound. For any fixed investigation depth m, A best-responds to G with a path of higher distance than G's investigation depth. In turn, G best-responds to A by matching the distance of A's transmission path. This goes up to $\overline{m}$, at which point G best-responds with a low depth $\underline{m}$. The best response cycle ensures that the equilibrium must be in mixed strategies and all of the depths in the range are played with positive probability.[31][32]

exceeds the recovery γ', so that $\overline{m}$ is finite.

[31] Our result on regulatory ambiguity is robust to incomplete information in the following sense. Suppose that the regulator has two types, a high and low maximum regulatory bound, $\overline{m}^h, \overline{m}^l$. If the likelihood of the high type is sufficiently high, then, for any fixed strategy m^h chosen by the high type regulator, agents best-respond with a transmission path of m^h+1, since this would always circumvent regulation. Following the provided argument, a best-response cycle would again arise.

[32] If insider profits could be scaled by sharing with multiple receivers, the optimal transmission strategy would entail a multi-path transmission strategy that extracted maximal information rents from trade. Without spillovers between investigations (that is, progress in one investigation facilitating others with involving duplicate nodes), then the strategy across path lengths for a given sender would not be consequential. However, if spillovers arise, then synchronizing the strategy for a given

Incurring a high enforcement cost is only justified conditional on detecting transmission or deterrence. When agents can anticipate high regulatory oversight, information is transmitted at long distances to circumvent investigations. At the same time, low regulatory oversight is justified if regulation is too costly. In the latter case, however, agents send and receive information at short distance, which could be detected with high oversight. As a consequence, the regulator must employ a mixed strategy with respect to the enforcement intensity in equilibrium. This formalizes the regulator's need to employ ambiguity in the form of a mixed enforcement strategy. Regulatory ambiguity arises when agents, in equilibrium, acquire access to a network that is able to successfully match senders to receivers through multiple paths of differing lengths.

This rationalizes a common strategy implemented and advocated by regulators to maintain vagueness in what constitutes illegal insider trading activity. For instance, legal boundaries of insider trading in the US are ambiguous and often criticized for being unclear. As a consequence, insider trading prosecution cases ultimately depend on courts to determine whether the nature of the shared information is in fact insider information, i.e. material and non-public, and whether the transfer of information is illegal, e.g. a violation of fiduciary duty. This flexibility in what constitutes illegal insider information is often argued by enforcement officers of the SEC as what allows for successful prosecution and even deterrence. A quote by Arthur Levitt, former chairman of the SEC, captures this sentiment:

> If the SEC had an option as to whether they wanted to have greater specificity and the Justice Department as well, they'd say 'Absolutely not' because greater specificity would give the legal fraternity various ways of getting around those specifics. They want these laws purposely vague to see to it they have the maximum leverage in terms of bringing cases.

It is worth noting that agents always transmit information as a consequence of $\overline{m} < \infty$. Marginal improvements to the regulator's competitive advantage, such as reducing its costs κ or increasing punishment γ does not fundamentally deter agents from transmitting information. Instead, these marginally improve the regulator's ability to operate investigations, thereby reducing social costs as agents are induced to transmit through longer paths.

sender may arise.

4.2 The Formation of Insider Networks

With the characterization of the optimal transmission strategy for a given network, we consider agents' network formation problem. We begin by noting several observations that help determine desirable properties of the equilibrium network. First, recall that the realizations of a sender and receiver pair occur after the formation of the network. This implies that if link costs are not prohibitively high, agents A prefer a network in which there exists a path between any $s \in S$ and $r \in R$, in order to ensure that inside information can be exploited.

As a starting point, consider the structure of a network that can efficiently propagate information between senders and receivers with the fewest number of links. A strong candidate is a *hub-spoke* network, which takes the form of a star-shaped network with a single hub node that is linked directly to all spoke nodes. This network emerges more generally, in the context of communication networks due to its scalability.

Agents must also anticipate the threat of regulation. As shown in Theorem 1, agents' optimal transmission strategy requires paths of varying degrees of depth. Notably, in the case of the hub-spoke network, all transmissions would be caught in investigations, as $\Delta_s = 1$. Thus, a desirable feature of the network is one that offers both sufficient obfuscation, i.e. paths with high depth, and flexibility in the available transmission paths between senders and receivers.

Consider a *core-periphery* network**,** which is similar to hub-spoke, but consists of a group of nodes (the "core") in place of the hub, and nodes (the "periphery") connected to the core in place of spokes. In addition to inheriting desirable features of a hub-spoke, a core-periphery may also extend the distance of paths within the core, thereby facilitating greater obfuscation. The need for flexibility in the amount of obfuscation inside the core necessitates a specific type of core. Consider a *tor-periphery* network topology, illustrated in Figure 3, and defined below:[33]

Definition. For any $k \geq \overline{m} + 1$, *a k-tor-periphery* network is defined as follows.

- There is k number of agents called the *tor*, denoted $T \subset I$.
  - Agents in the tor are called *relays*. There are three types of relays:

[33]The name comes from its close resemblance to The Onion Router (Tor) architecture, which is designed to solve related issues with regard to internet privacy.

Figure 3: Tor-periphery network

    - ∗ Sender relays: every link of each sender relay is with S or T and at least one link with S
    - ∗ Receiver relays: every link of each receiver relay is with R or T and at least one link with R
    - ∗ Middle relays: every link of each middle relay is with T
  - Tor provides *flexible obfuscation*: for every sender and receiver relay pair, there are paths of all distances[34] from $\underline{m}-1$ to $\overline{m}-1$ inside T that connect the pair.

- Every sender and receiver outside the tor is in the *periphery*.
  - Each sender in the periphery has exactly one link a sender relay
  - Each receiver in the periphery has exactly one link with a receiver relay

- Every link includes at least one relay.

We formally show that tor-periphery networks describe approximate equilibrium networks. Call a strategy $\left(L^*, \sigma_p^*, \sigma_m^*\right)$ an *ϵ-equilibrium* if for all L, p, m,

$$V_A(L^*, \sigma_p^*, \sigma_m^*) \geq V_A(L, p, \sigma_m^*) - \epsilon|A|$$
$$V_A(L^*, \sigma_p^*, \sigma_m^*) \geq V_A(L^*, p, \sigma_m^*)$$
$$V_G(L^*, \sigma_p^*, \sigma_m^*) \geq V_G(L^*, \sigma_p^*, m).$$

The first condition states that the average payoff of agents cannot be improved by more than ϵ by deviating from the network and the transmission strategy. The

[34] In general, a path in a simple network is defined as an ordered sequence of distinct nodes wherein each consecutive pair of nodes in the sequence is linked in the network. The distance of a path is defined as the number of nodes on it, other than the first and the last node.

second condition, however, states that a deviation from the transmission strategy alone cannot improve agents' payoffs at all.[35] Therefore, there is a sense in which the ϵ term in the first condition is due to the cost of links.[36]

Theorem 2. *For any $k > \overline{m}$ and $\epsilon > 0$, there exists $n^*_{k,\epsilon}$ such that if $|S|, |R| > n^*_{k,\epsilon}$ then any k-tor-periphery network is an ϵ-equilibrium network.*

There are several notable topological features of the tor-periphery networks not typically observed in core-periphery networks. As with any hub-spoke, the core facilitates transmission between different groups of the periphery agents, acting as relays between senders and receivers. However, within the core, intermediaries take one of three distinct roles, with sender relays serving as entry points for senders' information, middle relays forming the connective structure that provides varying degrees of depth, and receiver relays serving as exit points to receivers. This structure prevents any relay from being directly linked to senders and receivers, and allows for any potential pair between a sender and a receiver to be linked through varying paths. At the same time, middle relays are sufficiently connected to facilitate flexible transmission, thereby minimizing link formation costs. It is worth noting that in our setting, it is important for relays to be exclusively sender or receiver relays. This is because the regulator conducts investigations at the agent-level, by identifying a target agent and tracking their links and transmissions related to the insider trading investigation. As a result, this precludes the desirability of "loop"-like transmission paths, whereby information is transmitted from a single relay multiple times within a transmission chain.[37] Theorem 2 highlights that a small number of intermediaries can take on the role of intermediation on behalf of a disproportionately larger economy. In addition to retaining some properties of a hub-spoke to offer economies of scale in transmission, tor-periphery provides the necessary depth and flexibility for obfuscation to face regulatory ambiguity outlined in Theorem 1. Moreover, these costs become vanishingly

[35] We focus on the case in which agents coordinate on link formation. In the case of decentralized incentives, if links are verifiable, mechanisms such as exclusionary policies, in which those who do not form links as promised are punished through exclusion, could reinforce private incentives. Separately, with a sufficient number of intermediaries, it is possible that intermediaries would be willing to connect more than is optimal from the agents' standpoint, to be "flexibly" positioned within the tor to bid for participation in any transmission, leading to "over-connectivity" in the tor.

[36] We provide a discussion on multiplicity in this discrete model in Appendix C.

[37] We elaborate on this aspect in Appendix D. Interestingly, this principle is also true in the context of Tor networks used. For a single communication chain, entry and exit relays are distinct, and this distinction is essential because compromise in one or the other would not suffices to compromise the entire communication chain.

small relative cost of forming links as the number of senders and receivers increase. We explore this crucial feature of the network in the next section.

5 The Emergence of Intermediaries

5.1 The Case for a Continuum Economy

A key interest is to consider equilibrium dynamics with a large number of agents. In this section, we map the discrete environment to a setting with a continuum of agents. Before doing so, we briefly discuss several dimensions to consider as we move to the continuum case.

In our discrete model, the strategies employed by agents A and regulator G are exact best replies. We are able to characterize an equilibrium network by making use of the ϵ error-term in Theorem 2. Pinning down the exact optimal topology of links *inside the core* of the network is a non-trivial problem, but in important respects is inconsequential in a "macro-economic" sense. In particular, *the* striking feature of the ϵ-equilibrium network is outsized role that the set of intermediaries in the core plays to facilitate insider trading, relative to the cost of facilitating information transmission. This arises because the optimal $\overline{m}$, which determines the regulatory bound for any individual case, is invariant with respect to the number of agents. As the number of agents increase, the costs of forming the core make up a vanishing part of the total link cost. An implication is that the size of I can be kept bounded as the sizes S and R grow unboundedly.

A valid question is on the sensitivity of this feature to assumptions that might allow the network to scale with an increasing an increasing number of agents. For one, transmitting information is costless, and this allows agents to freely scale the number of transmissions. If transmitting information is instead assumed to be costly, costs associated with transmission would magnify with the number of agents. That is, however, without loss of generality – incorporating transmission costs would amount to reducing the per-transmission gain $\beta(\Delta_s)$ by an additional factor of distance Δ_s. Second, link costs are assumed to be linear and additive, which allows an individual agent to form a large number of links. If intermediaries instead face convex costs with respect to links, it could become too expensive for a highly connected intermediary to take on more links. In this case, I would also needs to grow unboundedly, but this would still be at a rate smaller than S and R. In this sense, the additive cost of links

is conducive to scalability, but is also not crucial.[38]

Thus, we view this feature, in which the number of intermediaries per sender and per receiver that can enable sufficient obfuscation to become vanishingly small in large populations, as a defining and robust insight. We build on this aspect foreshadowed in Theorem 2 by modifying the model to a continuum economy. As will be shown, the continuum approach offers tractability and starkly illuminates the outsized role that a select group of agents play to facilitate insider trading.

5.2 Continuum Baseline Model

We make several modifications in order to extrapolate Theorem 2 to a setting with infinite A. We first expand the set of senders and receivers. In particular, there is $\mu_S = \lambda(S)$ mass of senders and $\mu_R = \lambda(R)$ mass of receivers, in Lebesgue measure λ. The costs and benefits of A and G, other than the link cost, scale with population size as ζ fraction of S receive inside information, and payoffs V_A, V_G remain the same after replacing sums with integrals.

The main non-trivial aspect to modify is the cost of links. Proper accounting of the cost of links in a network on a continuum population needs significant care. In particular, uncountable zero-measure sets, such as Cantor sets, can potentially be exploited to lower network formation costs that are incongruent with the limit of any discrete case. For this reason, we impose that there is a finite *number* of intermediaries in I. With finite I and no links between non-intermediaries, we are able to account for each link accurately and once by indexing them with intermediaries. This assumed disproportion between the size of intermediaries and size of non-intermediaries is proven to be innocuous by Theorem 2.

An (undirected) *network* L is now defined as a (symmetric) measurable subset of A^2. Let $\mu_i = \lambda(L_i)$ be Lebesgue measure of $L_i = \{a : \{a, i\} \in L\}$, agents linked to $i \in I$. These cost $\eta\mu_i$. The costs of links within intermediaries is zero as the set I^2 is finite. Hence, the total cost of the network is given by

$$c(L) = \eta \sum_{i \in I} \mu_i.$$

This reflects what we observe in Theorem 2. The cost of links inside the core have vanishing relevance in a growing population. We maintain an analogous assumption that $\zeta\mu_S\beta(\overline{m} + 1) - \eta(\mu_S + \mu_R) > 0$.

[38] A similar argument holds for convexity in transmission costs.

We modify the definition of a *tor-periphery* network by changing each instance of "every" in the definition into "almost every," with respect to Lebesgue measure λ. By virtue of the continuum, we obtain a characterization result for the (exact) equilibrium in Theorem 3 as opposed to the sufficient condition for approximate equilibrium in Theorem 2.

Theorem 3. ***(Characterization of equilibrium networks)*** *A network is an equilibrium network if and only if it is a k-tor-periphery network.*

Admittedly, the equilibrium in continuum case does not put much discipline on the inner structure of the core, beyond flexibility for obfuscation. As such, it is possible, if not probable, that the continuum case does not describe the limit of the *exact* structure of connections inside the core of a discrete equilibrium. We view this as a *strength*, not a weakness. Our results show that the exact structure of links inside the core bears little consequence for aggregate outcomes, as long as it facilitates flexible obfuscation – an insight that is harder to appreciate when trying to identify "who should link who" in the (intractable) discrete case. For the remainder of the paper, we continue with the continuum model, which allows us to sharply characterize the dynamics between the agents A and regulator G. We acknowledge that this comes at the cost of abstracting over potentially interesting features that may emerge in the exact network structure of the core in a discrete environment.

5.3 Emergence of intermediaries out of non-intermediaries

So far, we considered an environment in which a set of intermediaries play a vital role in forming links and transmitting information between senders and receivers. However, a distinct feature in the context of insider trading is the emergence of intermediaries who specialize in helping insiders exploit inside information outside of regulatory oversight. To consider the endogenous rise of intermediation, we now extend the continuum baseline by (i) allowing links to be formed among all agents, and (ii) dropping intermediaries from the environment, i.e. setting $I = \emptyset$.

In the continuum baseline, I is assumed to be finite in order to rule out the possibility of zero measure uncountable sets from making up the core. In order to maintain an analog assumption, we assume sparseness. Formally, a network L is called *sparse* if only a finite number of agents have an infinite *number* of nodes, in counting measure. In sparse networks, there is a natural non-abusive method to count

the cost of links. Let F^* be the finite set of agents with infinite degree, η denote the cost of each link, and $d[a, Z, L]$ denote the number of links that $a \in A \backslash F^*$ has with members with $Z \subset A$ in network L. Then the cost of links is

$$c(L) = \int_{A \backslash F^*} \left(\frac{1}{2} d[a, A \backslash F^*, L] + d[a, F^*, L] \right) \eta \mathtt{d}a$$

That is, each link within $A \backslash F^*$ is counted twice, hence divided by 2. Each link between $A \backslash F^*$ and F^* is counted one. Links inside the zero measure set F^* have 0 cost. We obtain the following result:

Theorem 4. ***(Endogenous intermediaries)*** *Tor-periphery networks (in the sense that an endogenous subset $I^* \subset S \cup R$ takes on the role of I in the definition of tor-periphery networks) are equilibrium networks.*

A small set of agents endogenously specialize in providing flexible channels of information transmission and ultimately intermediate almost every (in λ) information transmission between the set of senders and receivers. This is, agents provide intermediation for other agents beyond the purpose of "scratching each other's back." Middlemen are necessary to tunnel and obfuscate transmission, and to avoid punishment.

5.4 The rise of intermediaries against social networks

Interestingly, the emergence of information intermediaries draws striking parallel to the rise of consultancy firms that have played an outsized role in recent years. While information intermediaries are legal, these consultancy firms have been implicated in a number of insider trading cases in the past decade. A large fraction of these firms is commonly referred to as expert network firms, which specialize in connecting clients to experts in various fields ranging from technology, medicine, healthcare, energy, and even economics.[39] What triggers the rise of such intermediaries?

Suppose that the agents are endowed with pre-existing social networks. Transmission over social networks is often uncoordinated and casual. There is no legal risk, but information is not kept confidential and diffuses to the market. This does not help to beat the market. Alternatively, social networks among close connections can be used for coordinated transmission but only across short distances. Coordinating long chains with secrecy and trust is not possible on casual social networks. On the other

[39] https://www.bloomberg.com/news/articles/2018-02-28/investors-are-paying-1-300-per-hour-for-expert-chats

hand, transmission over short distances is easy to document by prosecutors after a short search. The legal risk boils down primarily to detection risk.

We shed light on the migration of transmission activities from social connections to insider networks. We extend the baseline as follows. Each sender s has a given corresponding "friend and family" $f_s \notin A$. Each pair (s, f_s) share their payoffs equally. The pair can choose ex-ante to use their social connections to gain $\beta(0)$ by direct transmission, should the opportunity arise. If they choose so, they commit to each other, and s is excluded from the insider network. The (direct) transmissions in the social network are assumed to face an exogenous probability δ of an investigation. Alternatively, s can join an insider network and commit to equal sharing across all insiders, as in baseline environment.

We show that there exists a threshold δ^*, above which agents migrate their insider activity to a tor-periphery insider network:

Theorem 5. ***(Social and professional networks)*** *There exists δ^* such that in the unique efficient equilibrium, if $\delta < \delta^*$, all agents use social networks. If $\delta > \delta^*$, all agents switch to an insider network.*

The receivers in R are in fixed number and they are all insiders (without loss of generality). Then each insider sender's share of the total payoff of insiders is increasing in the number of insider senders. This makes the senders' decision to join the insiders complementary to each other. Accordingly, the highest possible per-insider payoff is achieved when all senders join the insiders. Therefore, the efficient equilibrium is when all senders join the insider network provided the resulting payoff exceeds a sender's alternative payoff from using its social network. This latter private payoff is decreasing in δ implying that for high δ, all senders join the insider network in the unique efficient equilibrium. When δ is low, even the highest possible payoff to a sender from joining the insiders is less than its alternative payoff from using its social network.

Theorem 5 forms the basis for the potential link between tightening regulation and the rise of information intermediaries. Major shifts in the regulatory framework in the early 2000s developed through Regulation Fair Disclosure (Reg FD), which was promoted by the SEC in 2000, and the Global Analyst Research Settlements, which was an enforcement agreement reached between the SEC, other regulatory agencies, and the ten largest investment firms in the US. Together, regulation focused on tightening

governance on information disclosure by public companies, and imposing controls on the leakage of material non-public information through financial intermediaries, such as research analysts and broker-dealers. What followed was dramatic growth in the expert network industry.

This relation between tighter regulatory control and the rise of information intermediation is also observed in the official sector. In 2012, the US Congress passed the Stock Trading on Congressional Knowledge Act (STOCK Act). The general intent of the law was to prevent government officials and employees from exploiting privileged access to non-public information that could potentially be used for financial gains. Following the passage of the STOCK Act, information intermediaries emerged in the form of political intelligence firms, which specialize in connecting clients to experts in areas of policy, law, and regulation.

A key takeaway from our model is that while these actions may succeed at displacing existing channels of information diffusion, they may prompt the formation of networks that undermine the main objective to improve market integrity. Furthermore, by providing a discrete channel of information transmission, these firms can also insulate clients from legal trouble, as the current regulatory framework requires proof of knowledge that the information constitutes inside information. A particularly eye-opening case is USA v. Blaszczak, in which defendants were convicted of selling and trading on political intelligence. In a divisive decision, courts ruled in favor of the defendants. The dissenting judge expressed concern over the impact of the ruling on its impact on insider trading:[40]

> The majority opinion effectively permits sophisticated insiders to leverage their access to confidential government information and sell it to the highest bidders – in this case, hedge funds that used the confidential information to make millions shorting the stocks of public companies affected by CMS's regulations.

5.5 Evolution of intermediaries in face of changing regulation

Theorem 5 highlights how tightening regulation can prompt the formation of insider networks in which bulk of information is intermediated by a small core. Once an insider network is established, how does it adjust to further tightening of the regulatory

[40] Court ruling can be found here.

environment? Our model presents one more stark insight. As a corollary of Theorems 2 and 3 , the tor can adapt to rising regulation by adding more intermediaries. New members are assigned to be middle relays, and need at most $\overline{m}+1$ number of links to pre-existing relays in order to provide additional flexibility to the entire ecosystem of insiders. As new relays do not need to be sender or receiver relays, the bulk of the network cost is already paid up.

Improving the extent of potential obfuscation in face of tightening regulation (maximal depth $\overline{m}$ or detection δ) needs vanishingly small cost, relative to regulators' costs. In this sense, there is no level of regulation that the agents cannot adjust to, as long as $\overline{m} < \infty$ and $\zeta\mu_S\beta(\overline{m}+1) - \eta(\mu_S+\mu_R) > 0$. If the first is reversed by a downward shift in costs κ, Theorem 1 no longer holds. The "winner" of the war of attrition shifts from A to G. If the first condition holds but the second fails, even though Theorem 1 holds, the network cost does not support the continuation payoffs. In either case, regulation becomes more *effective*: there is a positive probability of not transmitting information.

6 Extensions and Robustness

6.1 Legal boundaries

It is worthwhile highlighting how our setting also offers a foundation for laws that may be deliberately set broadly so as to avoid gaming by agents. In our main setting, the regulator is able to punish agents as long as an investigation maps the transmission path between the sender and the receiver. Alternatively, suppose prior to information transmission, lawmakers select a boundary strategy b, which determines the maximum path length between a sender and receiver that constitutes illegal insider information if used for financial gains. For instance, if $\Delta_s \leq b$, transmission may be regarded as a deliberate transfer of information intended for illegal profits; if $\Delta_s > b$, the communication between the sender and receiver may be deemed too distant to constitute illegal activity.

Correspondingly, suppose that any given b is associated with a cost $\beta(b)$, where $\beta(b)$ is a strictly increasing function associated with the social cost of violating of investors' civil liberties and privacy. This reflects the idea that the legal boundary b confines the regulator's ability to explore whether illegal insider trading occurred. For example, a regulator may require authorization from a judge to search, confiscate,

and analyze evidence. The scope of any particular investigation would then be limited to the legal boundary b. For simplicity, we suppose that $\kappa(m) = 0$ for any m, but the set of feasible m is bounded above by b. Accordingly, the regulator would set m to equal b.

It is straightforward to see how the arguments underpinning Theorem 1 may carry forward. As long as agents have sufficiently complex networks that facilitate long transmission paths, lawmakers' equilibrium boundary strategy must be a mixed strategy over a set $[\underline{b}, \overline{b}]$, for some thresholds $\underline{b}, \overline{b}$, where $\beta(\underline{b}) = 0$, and $\beta(\overline{b}) \leq B < \beta(\overline{b} + 1)$.

Given this interpretation, Theorem 1 rationalizes a common practice of maintaining vagueness in what constitutes illegal insider trading activity, and instead rely on the judgment of courts on a case-by-case basis. A corollary is that any shock to the legal framework, which increases the costs associated with prosecuting insiders using longer chains necessarily raises the profitability of insider trading. As a direct test of this prediction, Pierce (2023) finds decisive evidence of this – following New York Second Circuit ruling on US v. Newman, which raised the burden of proof for punishing traders with "remote" links to the source, the trading performance of traders in the Second Circuit of *Second Circuit firms* significantly improved.

6.2 Regulatory investigation costs

In the baseline model, the regulator faces a cost $\kappa(m_s)$ that depends only on the maximum depth m_s of an investigation. Depth determines how far an investigation can extend beyond the original insider, receiver r_s. This formulation of the cost structure is motivated by several institutional regularities. First, as explained earlier, the regulator faces a higher burden of proof in the network distance between the sender and receiver. Second, the regulator typically does not observe the underlying network, and thus must incur investigate costs associated with gathering and extracting information regarding each individual and their links along a transmission chain. Hence, investigative costs should increase as the regulator expands the scope of its investigation. More generally, it constrains the extent to which the regulator is able to devote resources to a particular investigation. The existing literature on insider trading regulation documents compelling evidence that enforcement agencies, such as the SEC, are not only heavily constrained in resources Kedia and Rajgopal (2011), but also inelastic Ahn et al. (2024), and are only able to investigate a small fraction

of total incidences of insider trading (Augustin et al., 2019; Patel and Putniņš, 2023).

In the model, the regulator is unable to directly observe the network. In an investigation, the regulator expands their view into a network by investigating all links of a targeted agent. Through this process, the regulator discovers links involved in transmitting information, and extends their investigation to another agent. Thus, a direct interpretation of the regulatory costs is the total cost associated with a fixed cost per targeted agent and a variable cost per targeted agents' links. In this section, we consider this explicit cost structure that depends on the number of agents and their links, focusing on the continuum model.

Consider the following modification of the regulatory cost. Instead of $\kappa(m_s)$, let the regulatory cost depend on the number of agents investigated beyond r, a_m, and the measure of their links l_{a_m}, so that

$$\hat{\kappa}(a_m, l_{a_m}) = c_a a_m + c_l l_{a_m},$$

for some $c_a, c_l \geq 0$.[41]

Although we specified the above cost function for the continuum case, it is useful to consider how the costs are accounted for in an example. For concreteness, consider the network and transmission in Figures 1 and 2, and let the cost c_l be associated with the number of links.[42] In the first example, the regulator starts the investigation with r_s and their links. Starting the second round, the investigation becomes costly: the regulator investigates 2, incurring c_a and c_l for each of the 4 links (excluding that with r_s). In the next round, the regulator investigates 1, incurring an additional c_a and $3c_l$ for their links, and confirms a path between r_s and s. In total, the regulator incurs $2c_a + 7c_l$. In the second example, the regulator incurs $3c_a$ associated with investigating agents, and $8c_l$ associated with their links, but fails to establish a path between r_s and s.

One implicit consequence of a depth-based investigation cost is that the regulator can explore any and all transmission paths, as long as they are within a certain depth. Consequently, agents' transmission strategies primarily hinge on path length

[41] The specific linear formulation is chosen purely for expositional purposes. Here, we set the investigation cost associated with r and their links to be zero to be consistent with our baseline assumption that $\kappa(1) = 0$.

[42] To be precise, discrete counterpart of the continuum-setting link costs should be $\frac{c_l}{n}$, where n is the number of agents, so that the cost of countable links approaches zero in the limit. In contrast, the agent-level costs do not require any normalization, and as argued, are key to the emergence of non-trivial network structure.

and their is no motive to transmit along multiple path. On the agents' side, we expand on how transmissions impact insider payoff. Empirically, trade profitability is shown to decline with path length, with one key explanation being that it is more likely to leak along the transmission path (Ahern, 2017; Patel and Putniņš, 2023).[43] To properly account for the impact of multiple transmissions on insiders' payoffs, we modify the payoff function to be $\beta(\sum_p \Delta^p)$, where $\sum_p \Delta^p$ is the total sum of the depth of transmission path p used by insiders. This rules out perverse circumstances where insiders could use arbitrarily many transmission paths without penalty, which are plainly at odds with our main applications of interest.

We make several remarks:

Remark 1. **(Transmission paths)** In contrast to the baseline case, investigation costs are explicitly affected by the number of agents and the number of links. This introduces a new strategic dimension for agents to potentially increase investigative burden through their transmission strategy. If we maintain the assumption that the regulator begins an investigation with r_s, then the use of multiple transmission paths do not fundamentally change equilibrium dynamics. First, any transmission from s that does not reach r_s has no effect on the scope of the regulator's investigation. Second, with multiple transmissions connecting s and r_s with the same path length, the regulator can select any path at random. Then, the ex-post costs associated with an investigation could in principle vary, but the expected investigation costs would be impacted by the number of links not different from how it would be for a single transmission path. Finally, consider the case with multiple transmissions with different path lengths. To fix ideas, consider when insiders use two paths with n_1 and n_2 agents along the path. In this case, the regulator can ensure that they successfully unravel at least one of the paths by investigating at most $\max\{n_1, n_2\}$. This strategy is dominated by the use of a single path with $n_1 + n_2$ agents, which yields the same payoff but requires the regulator to incur at $n_1 + n_2 > \max\{n_1, n_2\}$.

Remark 2. **(Link costs)** Here, we specified a "symmetric" treatment with respect to the link formation costs and link investigation costs, whereby the investigation costs associated with individual links are negligible.[44] Moreover, since the set of agents in

[43] This is also consistent with the underlying motivation for diminishing returns from path length in the trading-based extension in Appendix A.

[44] As a side note, this does lead to a somewhat awkward scenario in which as the number of agents increases, the regulator faces a shrinking cost of investigating individual links between agents. Despite this, this formulation proves to be instructive in understanding what aspect of the costs are

core is assumed to be finite, the link-level costs in the tor are trivial. The network can, however, maximize l_{a_m} for any investigation by forming a tor-periphery with as few sender and receiver relays as possible.

With these two observations, let us consider two cases on the cost structure. First, we can see there is a clear requirement on the cost structure in order for our results to hold. Whenever $c_a > 0$, there exists a mapping from $\hat{\kappa}(a_m, l_{a_m})$ to some $\kappa(m)$, i.e. regulatory costs $\hat{\kappa}(a_m, l_{a_m})$increases in depth. Consequently, our results (along with some basic conditions on payoffs) carry over with this modified regulatory cost. This demonstrates that the underlying tor-periphery network structure emerges as long as the regulator faces some costs associated with investigating a greater number of agents.

Next, consider the case in which *only* link-level costs matter, i.e. when $c_a = 0$. Roughly speaking, in this case, the regulatory burden of investigating a sequential chain of l agents is identical to a $l-1$ direct links. This type of cost structure deflates the need for any transmission path of meaningful length. In the continuum model, investigation depth only matters to the extent that adding an additional agent increases the regulatory costs associated with the transmission.[45] Furthermore, this is only possible when an agent has a positive measure of links. In particular, let $\bar{l}$ be the maximum measure of links such that G's payoff conditional on successful enforcement is nonzero. As long as agent's payoff conditional on not getting caught is positive net of $\eta\bar{l}$, then agents can form a network such that between any two sender and receivers, there exists a path with a total measure of links $\bar{l}$. As such, path lengths are no longer pivotal and the game becomes a war of attrition through link formation. For illustration, let $\bar{l} \in (\lambda(S)+\lambda(R), 2\lambda(S)+2\lambda(R))$. Note, the maximum links for a single agent is $\lambda(S) + \lambda(R)$. Because a single agent alone cannot impose sufficiently high link costs to the regulator, the network must have two agents serving as relays, and where each relay is fully connected to S or R, and partially connected to the other group until the total mass of links becomes $\bar{l}$. This shows that with only link costs, the core tension of circumventing regulation by creating distance between the source and user of inside information becomes secondary to the main motive to form links purely to make investigations more expensive.

important for our key results.

[45]Moreover, insiders never form links that they never use, since the network is unobserved and they could cut those links to save costs without affecting any outcomes.

6.3 Targeting the tor and whistleblowing programs

A resounding implication of our analysis is that a small set of relays play an outsized role in transmitting information on behalf of the network. Moreover, through multiple layers of middle relays, the tor is able to flexibly extend the length of the transmission chain. This makes it particularly challenging for the regulator, who faces an increasing cost with respect to investigation depth, working in from the receiver r_s. In principle, the regulator would want to conduct a deliberate investigation that not only targets the receiver r_s, but other key relays that are likely to be involved in a particular transmission. A key limitation is that the regulator is unable to directly observe the network. This feature of our environment is consequential: the regulator is limited in their ability to identify key players in the network because their identities are not known ex-ante. This explains the implementation of whistleblower programs, which publicly solicit information in exchange for rewards in order to reach agents who they would not know otherwise.[46] As such, even with a fixed set of potential intermediaries I, the regulator would need to target a large group of agents.

This raises the question of how alternative enforcement strategies that target agents in the tor might impact the efficacy of the regulator. In this section, we consider an extension of the model whereby the regulator is endowed with a tor-enforcement technology that is able to target the tor in order to extract intermediate transmissions within the chain. In the background, we have in mind the introduction of a whistleblower program, through which an insider voluntarily shares information about the use of inside information to the regulator.

We extend the model to consider a such technology. Specifically, suppose that the regulator can now infiltrate one "active" middle relay on the transmission with some probability $h > 0$. Under infiltration, the regulator identifies two additional agents directly linked to the middle relay. In effect, for a transmission path of depth d, the regulator can now successfully enforce the case if $\bar{m} \geq d - 2$.

An immediate consequence of the tor-enforcement technology is a "deterrent" effect: it forces agents to use longer transmission paths and deters agents from more egregious use of inside information. As insiders increase the average depth of their transmissions, and specifically extend the maximum transmission by two additional steps, insider trading becomes less profitable. Second, the technology has an "enforce-

[46] In contrast, intermediaries found to be implicated in an insider trading scheme through an investigation do not reap such rewards.

ment power" effect: it directly contributes to ex-post enforcement, and in particular, with complex cases involving long transmission paths.

Indeed, the limitations of traditional investigation techniques were recognized and motivated the US Congress to create the SEC's whistleblower program in Dodd-Frank Act of 2010. The whistleblower program, one of the most significant changes to regulatory enforcement to date, incentivizes insiders to voluntarily disclose original information on securities law violations, including insider trading, by providing monetary incentives and protection from retaliation. Both the deterrent effect and the enforcement power effect are empirically corroborated. Raleigh (2020) studies the impact of whistleblower programs and finds strong evidence of it impacting the profitability of traders likely to be affected by whistleblower programs. Although a specific breakdown is not publicly available, the SEC's whistleblower program has recovered over 6 billion dollars relating to securities law violations as of 2022. These bolster arguments that whistleblower programs, despite the hefty bounties offered to whistleblowers, may be complementary to existing investigative tools. While considering the optimal implementation of a whistleblower program is outside the scope of this paper, this extension supports the idea that a whistleblowing program can strongly complement existing enforcement tools.

6.4 Direction of investigation

Our preferred narrative is that investigations start with either a sender or receiver, who is suspected of illegal activity. However, our setting allows for investigations to start at either end of a transmission path, depending on the monitoring technologies deployed. We outline how our results carry over with a modification.

Suppose only traders are observed. Then A can use pure strategies for transmission at any pair, as long as the combined probabilities on path distances conditional on any given trader correspond to probabilities in the baseline equilibrium mixed strategy. That is, flexibility is now needed only at each trader, not at each pair. Consequently, almost every pair must be connected with one path that has distance among $\underline{m}+1$ to $\overline{m}+1$. Conditional on any trader, the measure of senders with each corresponding path depth must be selected in accordance so as to add up to the baseline equilibrium probability for each path distance. Furthermore, the equilibrium network is still given by tor-periphery, with an appropriately modified flexible obfuscation condition.

7 Conclusion

In this paper, we study a model of endogenous formation of networks over which agents transmit information under regulation. In equilibrium, the regulator implements regulatory ambiguity that induces agents to take greater risks in information transmission. Agents adapt to regulation by forming a flexible network with a core-periphery structure, which endows agents with the option to transmit information through various paths of differing length.

We show how the core represents the endogenous rise of information intermediaries. A small set of agents that form the core of the network intermediate information between potential senders, i.e. insiders, and receivers, i.e. those that seek to exploit information. In an extension, we show that tightening regulation can trigger agents to migrate transmission activity from social networks to an insider network. We draw parallels to the recent growth of the expert network and political intelligence industry following stricter regulation regarding disclosure and insider trading. The surge of information intermediaries suggest that rather than curtailing insider trading, market participants may have adapted by developing alternative and more complex channels through which insider information is shared and exploited.

As a final note, we believe that our setting is applicable to a broader set of problems. In particular, the model can be used to understand network design problems, in which agents want to transmit messages or goods, but must combat a strategic actor (as in our case) or exogenous risks. Many networks involving communication or information sharing require achieving a sufficient level of security and privacy. An efficient network entails safeguarding the anonymity of messages from a malicious attacker while economizing on the cost of building and using the network. The model can be extended to study trading networks, in which agents prefer trading in proximity, but face counterparty risk. In particular, we highlight potential benefits of having a core-periphery structure that allows for intermediaries to flexibly re-direct flow between counterparties. We leave these applications for future research.

A Insider Trading in Financial Markets

In this section, we extend the model to allow for insiders to trade directly in financial markets, in effect endogenizing $\beta(\Delta_s)$ and $\gamma(\Delta_s)$.

Insider Information and Transmission. There is a financial market where agents can trade an asset with some fundamental value θ, where θ takes a value 1 or 0 with equal probability. Let the sender s be perfectly informed about θ. Suppose that the sender s transmits information regarding θ to the receiver r_s along a path of depth Δ_s. We assume that longer transmission poses a higher risk that s's information becomes public, i.e. nonmaterial, before trading is executed. One interpretation is that information is more likely to leak along the transmission path as information is passed through more agents. Alternatively, transferring information may take time, and a longer path increases the likelihood that transmission does not occur in time for profitable opportunities. Then, the likelihood that transmission provides r with an informational advantage is given by $\rho(\Delta_s)$, where $\rho(\cdot) \in [0, 1]$ and $\rho(\cdot)$ decreases in Δ_s. With $1 - \rho(\Delta_s)$ probability, then θ becomes common knowledge, i.e. the market-maker becomes informed.

Financial Market. The market is populated with the receiver, a market-maker, and noise traders. If the receiver gains an informational advantage, the receiver makes a market order $x \in \{1, -1\}$. Noise traders' demand is stochastically determined $\tilde{y}$ drawn from uniform distribution $U[-y, y]$, where $y > 1$. The market-maker observes

total demand $X = x + \tilde{y}$, where $x = 0$ if the receiver chooses not to trade. The market-maker sets price $P = E[\theta|X]$. Given price P, the payoff from trade for the receiver is given by $x(\theta - P)$. Finally, the regulator is assumed to observe individual order flow, i.e. x. This implies that as long as $x \neq 0$, the regulator initiates search. If the regulator initiates a search and catches agents, a punishment γ is imposed.

The solution to the trading game is characterized below:

Proposition 1. *In the trading game equilibrium, the expected profits from transmitting on a path of depth Δ_s are given by $\beta(\Delta_s) = \rho(\Delta_s) \cdot \frac{y-1}{2y}$.*

Proof. We conjecture and verify that if if informed makes order $x = 1$ if $\theta = 1$, and $x = -1$ otherwise. Given this, the market-maker observes total order flow $X = 1 + \tilde{y}$ if $\theta = 1$ or $X = -1 + \tilde{y}$ if $\theta = 0$ if transmission successfully occurs. Given this, prices are given by:

$$E[\theta|X] = \begin{cases} 1 & \text{if } X > -1 + y \\ \frac{1}{2} & \text{if } X \in [1 - y, -1 + y) \\ 0 & \text{if } X < 1 - y \end{cases}$$

The profits of the receiver if informed is $\frac{y-1}{2y}$. It is straightforward to see that deviating is not profitable. Given a transmission over a path of length l, the receiver's expected payoff is given by $\Pi(\Delta_s) = \rho(\Delta_s) \cdot \frac{y-1}{2y}$, and the expected social externality cost of $\rho(\Delta_s)\gamma(\Delta_s)$. □

The trading game provides a microfoundation for how insider trading profits are inversely related to the length of the transmission path. In equilibrium, the market-maker is less informed than the receiver with probability $\rho(\Delta_s)$. This in turn affects the ex-ante expected payoff from transmitting through a path of depth Δ_s. Embedding this result in the rest of the model, we can see that the core intuition from the main model follows. The sender and receiver face a tradeoff between transmitting information with higher expected value and the higher likelihood of prosecution (i.e. $Prob(m \geq \Delta_s)$ decreases in Δ_s).

B Decentralized Protocols

B.1 Decentralized transmission and the burden of proof

So far, we assumed that insiders chose the optimal transmission path to exploit inside information. Implicitly, this assumes that insiders, including the sender and receiver,

are coordinating, either through instructions or communication, on the transmission path for inside information. By knowing the source of the information, intermediaries along the chain demonstrate implicit knowledge that the transmission constitutes inside information. In the context of the model, this considerably simplifies the burden of proof for the regulator. First, verifying the transmission path connecting the sender and the receiver is sufficient for the regulator to prove that all agents, including the receiver and intermediaries, knowingly shared inside information for the trading purposes. Second, it also provides tangible link between the sender and receiver, thereby rendering any transfers to the sender enough to meet the condition of "quid pro quo". As such, the two parts to the burden of proof, namely, knowledge that the information traded on constitutes non-public material information, and benefits shared between those along the insider chain. In practice, however, inside information is often shared across the network in a decentralized manner (without explicit instructions on how to transmit information), and without explicit knowledge that the tip entails inside information.

In this section, we take as given a tor-periphery network, and consider an explicit implementation of optimal transmission strategy that could be employed by agents in a decentralized manner, and explore its implications on regulatory enforcement. At a high level, agents individually decide on who to pass information to, and use a message that contains only limited information about the providence of information. We demonstrate that insiders are able to replicate complex transmission strategies with only limited information, and explore how its strain regulators' ability to meet the burden of proof, further limiting enforcement intensity in equilibrium.

Decentralized Transmission. Instead of selecting path p_s, we assume that at the transmission stage, each agent chooses who and how to send information. Specifically, at the transmission stage, suppose that agents can transmit information only using a *tip* $\omega(\theta_s, a, \tau)$, which contains the inside information θ_s of sender s, the recipient $a \in A$, and the context τ, which explicitly conveys information about the nature of θ. The set of τ can be arbitrarily large. We will consider the simplest case where $\tau \in \{\star, \varnothing\}$,where $\tau = \star$ indicates that the original source is from S, and otherwise $\tau = \varnothing$, which also offers an economic interpretation of whether the recipient has demonstrable knowledge that θ_s constitutes inside information.

In our baseline model, agents select some path $p_s(s, i_1, i_2, ..., i_{\Delta_s}, r)$, which equivalent to a sequence of tips $\omega(\theta, i_k, \star)$ for $k = 1, 2, ..., \Delta_s$ and $\omega(\theta, r, \star)$. With decentral-

ized transmission, agents lose several pieces of potentially vital information. First, aside from the first intermediary i_1 who receives a tip directly from s, intermediaries who receive tips are no longer have direct information regarding the providence of the inside information (i.e. the identity of s). Second, intermediaries no longer have direct information regarding their exact position within a transmission chain. Instead, they only know the identity of the agent who sends the tip to them, who we refer to as the *tipper*.

We first want to show that agents are able to achieve the optimal transmission strategy with decentralized transmission. Recall, in equilibrium, agents mix between a set of paths that span depths from $\underline{m}+1$ to $\overline{m}+1$. For expositional purposes, let us focus on when $\kappa(\cdot)$ is such that $\underline{m}=1$ and $\overline{m}=4$.[47] In order to implement the optimal transmission strategy, there must exist a rule that allows a sequence of agents to choose tips that can replicate the mixing strategies on paths of varying distances. We prove by example in the following proposition:

Proposition 2. *Consider the following rule:*

1. s sends $\omega(\theta, i_k, \star)$

2. If tipper is from S, i_k sends $\omega(\theta, i_{\Delta_s}, \varnothing)$ with probability p_3^1; $\omega(\theta, i_k, \varnothing)$ with probability p_4^1; and $\omega(\theta, i_{k'}, \star)$ with probability p_5^1 where $k \neq \Delta_s$

3. If tipper is a sender relay, i_k sends $\omega(\theta, i_{\Delta_s}, \varnothing)$ if she receives $\omega(\theta, i_k, \varnothing)$. Instead, if she receives $\omega(\theta, i_k, \star)$, she sends $\omega(\theta, i_{k'}, \varnothing)$ with probability p_5^2; and $\omega(\theta, i_{k'}, \star)$ with probability p_6^2, where $k' \neq \Delta_s$ and not hub.

4. If tipper is not in S and not a sender relay, i_k sends $\omega(\theta, i_{\Delta_s}, \varnothing)$ if she receives $\omega(\theta, i_k, \varnothing)$; and $\omega(\theta, i_{k'}, \varnothing)$ if she receives $\omega(\theta, i_k, \star)$, where $k' \neq \Delta_s$ and not hub.

5. i_{Δ_s} sends $\omega(\theta, r, \varnothing)$.

Using this rule, agents can implement the equilibrium transmission strategy.

Proof. **(Proposition 2)** The implied probabilities of all path lengths are given by p_3^1 for $l=3$, p_4^1 for $l=4$, $(1-p_3^1-p_4^1)p_5^2$ for $l=5$, and $(1-p_3^1-p_4^1)(1-p_5^2)$ for $l=6$. Hence, for any mixing strategy with $p_1, p_2, p_3, (1-p_1-p_2, -p_3)$ corresponding to transmission paths with depth $l=3,4,5,6$, the rule can match probabilities by setting $p_3^1=p_1$, $p_4^1=p_2$, and $p_5^2=\frac{p_3}{(1-p_3^1-p_4^1)}$. □

[47] First, this path length coincides with those empirically observed in some of the most sophisticated insider trading cases to date (Ahern, 2017). However, we provide a discussion at the end on how a richer set of ι would be operative in practice and support much larger transmission strategy sets.

The rule outlined in Proposition 2 shows that tips, combined with information about the identity of the tipper and network, is sufficient for agents to replicate any equilibrium transmission strategy.

There are several notable observations of Proposition 2. Appending the context of insider information to a tip, i.e. tips with $\tau = \star$, informs the tippee that θ_s should be passed along further. Doing so enables intermediaries to achieve transmission paths of varying lengths ex-post with fairly simple rule. Interestingly, in the last several tips along *any* path, agents avoid communicating the context. In doing so, with decentralized transmission, omitting the providence of θ in a tip acts as a signal that tip should be used for trading. Whenever an intermediary receives a tip with $\tau = \varnothing$, the intermediary tips the intermediary directly linked to a trader who can exploit the information.

Additionally, the simple rule not only facilitates optimal transmission, but achieves a deeper purpose in the context of insider trading because the regulator faces the burden of proving the trader's knowledge of insider information. The practice of sharing information whilst deliberately avoiding details on its insider nature is documented in real-world practices in insider trading. In the pivotal case of United States v. Newman, the Southern District of New York convicted a group of portfolio managers, analysts, and corporate insiders, who were accused of exploiting insider information. Despite clear evidence on the path of information transmission, the defendants successfully appealed their case based, among several issues, on the fact that [48]:

> [The] Government presented no evidence that Newman and Chiasson knew that they were trading on information obtained from insiders in violation of those insiders' fiduciary duties.

In other words, without explicit proof that a tippee communicates the insider nature of the tip, the ultimate beneficiary of insider information can credibly argue that they knowingly traded on nonpublic, material information.

To appreciate the impact of this on equilibrium outcomes, consider the following extension. Let agents follow the rule in Proposition 2, and suppose that whenever information is transmitted without sharing its fidelity (i.e. $\tau = \varnothing$), regulators incur an additional cost $\overline{\kappa}$. That is, absent direct proof that a tippee knows the original source of the tip, the regulator may need to devote greater resources to build a case

[48] See here for more details.

around circumstantial evidence. The expected cost of enforcing $\overline{m}$ rises by more than $\overline{\kappa}$, since all paths involve at least one tip with $\tau = \varnothing$. When the cost function $\kappa(m)$ shifts upward sufficiently high, the regulator is forced to lower $\overline{m}$. In effect, the average transmission path decreases, and insider profits increase in equilibrium.

B.2 Alternative decentralized transmission mechanisms

Proposition 2 outlines an implementation of decentralized transmission in the context of tor-periphery networks. In this section, we further consider a more general decentralized transmission protocol that could achieve secure communication over trusted links.

As a precursor, links in L represent trust that is formed at cost in the past. Embedding trust in links is key for the machinations of insider networks along several dimensions. In practice, it helps to mitigate regulatory risk by maintaining the confidentiality of information transmission and discouraging whistleblowing and/or cooperating with authorities. It also facilitates efficient exploitation of insider gains by ensuring the reliability and accuracy of information, and avoiding diversion for private gains.

Consider the following protocol among trusted agents. Agents agree on a modus operandi M to facilitate inside information transmission. $M : A \times A \times \Theta \to A \cup \{\emptyset\}$ is a codex describes local 'next steps' during transmission. If nature gives a receiver $r \in R$ an opportunity in θ, making $r = r_\theta$, then r knows that r should

Given L, the search and transmission of information is facilitated via a *modus operandi* M, described as follows. We start by considering a scenario, in which $r_s \in R$ seeks inside information. If r_s wants an "opinion" on some matter θ, r knows that r_s should

- Ask a trusted intermediary $M(r; r, \theta) \in L_r$: "What is your opinion on θ?"
- If $M(r; r, \theta) = \emptyset$, do not ask anyone.

When $a \in A$ is asked "What is your opinion on θ?" by a trusted agent $a' \in L$, then a knows that a should

- Not ask a' why opinions on θ is needed,
- Ask trusted agents described by the codex $M(a'; a, \theta) \in L_a$, "What is your opinion on θ?"

- Report the opinion back to a' once it is provided by $M(a'; a, \theta)$.[49]
- Not share the opinion with anyone else.

When $s \in S$ is asked for an opinion on θ by a trusted agent $a \in L$, then s knows that s should

- Not ask a why an opinion on s is needed,
- Provide an honest opinion if s knows θ.

The modus operandi M is a codex that describes instructions for mutually trusting counterparties in L. It is an ex-ante communicated methodology on how to communicate ex-post. In this particular scenario, requests for information held by s flows from r_s to s along the chosen path. Then information flows back along the same path once obtained from s.

A similar methodology can be used in an alternative scenario in which an expert s initiates the chain. When s_θ receives the inside information, s knows that s should ask a trusted intermediary $M(s; s, \theta) \in L$: "Do you want my opinion on θ?" When $a \in A$ is asked "Do you want my opinion on θ?" by a trusted agent $a' \in L$, then a knows that a should hear the opinion and ask a trusted agent described by the codex $M(a'; a; \theta) \in L$, "Do you want my opinion on θ?" When $r_s \in R$ is asked "Do you want my opinion on θ?" by a trusted agent in L, r_s should hear the opinion and trade on the information.

Mixtures of the two scenarios also work. Asking for information can start from r_s and offering information can start from s. Ultimately, any execution boils down specifying a path of transmission. That is, choosing codex M is equivalent to picking, for each case θ, either not to transmit, or to pick a transmission trail r_s and s in L

$$p_\theta = (r_s, i_1, i_2, ..., i_\Delta, s) =$$
$$\Big(r_s, i_1 = M(r_\theta; r_\theta, \theta), i_2 = M(r_\theta; i_1, \theta), ..., i_{k+1} = M(i_{k-1}; i_k, \theta)), ..., s = M(i_{\Delta-1}; i_\Delta, \theta)).$$

Note that M in and of itself does not rule out trails that overlap with itself. For example, it is possible that $i_1 = i_3$. But this only makes the required investigation shorter. So it is without loss that M that leads to a non-path trail would never be picked. Furthermore, any randomization needed for path lengths is handled by randomizing M.

[49] Alternatively, the codex can describe who to refer to next.

B.3 Decentralized Compensation Schemes

In the baseline model, we assume that agents A shared the costs and benefits from insider information. In reality, redistribution of payoffs, particularly in the form of payments, poses a significant risk to agents due to traceability. As such, in practice, insiders may dynamically exchange tips instead, sharing information to the network in anticipation of receiving tips in the future (Tamersoy et al., 2013). In a dynamic version of our setting, this could arise if agents alternate between being senders and receivers over time. In other contexts, however, traders may explicitly seek to pay for access to inside information. For example, in the cases involving expert network firms, hedge funds sought contact with corporate and legislative insiders to extract material non-public information, which was relayed by intermediaries at a price.[50] Motivated by this, we outline a simple protocol that achieves both decentralized transmission and compensation scheme.

Specifically, consider the following scenario in which inside information is actively sought out by a trader. suppose that each sender and intermediary are simply paid a fixed amount in exchange for their 'expert opinion.' There is no implicit distribution and sharing of private gains of traders. Instead, there is an implicitly agreed upon 'market rate' q_0 for information origination and q_1 for information relay. Consider the following scheme:

- The trader seeking information from a path of distance Δ, offers to any linked intermediary to pay for 'advice' at price $q_0 + \Delta q_1$, such that price maps to the intended path length: $\frac{(q_0+\Delta q_1)-q_0}{q_1}$.
- The intermediary picks any random intermediary and offers to pay $q_0+(\Delta-1)\,q_1$ for 'advice.' Note, i_1 pockets q_1.
- A random sequence of questions continues until an intermediary is offered $q_0 + 2q_1$.
- This intermediary asks someone who is linked to the expert of the topic and offers $q_0 + q_1$, pockets q_1. The final intermediary, upon observing that he is offered $q_0 + q_1$, asks the expert, offers q_0 and pockets q_1.
- The expert accepts, provides its 'opinion,' which flows back along the path as agreed upon in the trade. Note that if an intermediary has been asked and has

[50] In the context of compensation, networks in which intermediaries form a coalition at the core may have additional benefits arising from allocative efficiency (Gofman, 2011).

received payment before, he is trusted to refuse additional offers. When an offer is refused, the offering intermediary asks another intermediary at random until it finds one who accepts.

This protocol requires that links in L represent trusted relations, (ii) prices q_0 and q_1 are determined ex-ante, and (iii) for each $s \in S$ and $i \in I$, there is $j \in I$ such that $\{i, j\}, \{j, s\} \in L$ and i knows that $\{j, s\} \in L$, the last of which is satisfied if and only if the network is a tor-periphery.

C On the Multiplicity in the Discrete Model

In this section, we discuss the multiplicity in the discrete case, which is permitted under the ϵ-equilibrium concept.

First, a reasonable question is whether there is a uniquely optimal equilibrium network. We conjecture that (under reasonable conditions) the structure of all equilibria are closely related to a specific tor-periphery structure that takes a "candy" shape. Specifically, a candy tor-periphery is a tor-periphery network where all senders connect to one intermediary i, all receivers to another intermediary j, and a remaining subset of intermediaries form paths of various lengths (to ensure flexibility) between i and j.

To start, observe that there is always a "candy equilibrium." For any given equilibrium, rewiring the links of each sender to one sender-relay, say i, and rewiring the links of each receiver to one receiver-relay, say j, turns the structure into a candy shape with two relays i and j. Since the original configuration is an equilibrium network, i and j provide flexibility. The number of links remains the same. So the new candy structure is also an equilibrium network.

The equilibrium candy tor-periphery involves the fewest number of relays (namely, one sender and one receiver relay) linked to a sub-network of intermediaries with the minimum number of links needed to achieve flexibility. Since all senders and receivers depend on this sub-network, every single link is used in at least one path between any sender-receiver pair. This makes such network structure a sensible candidate equilibrium for uniqueness. For example, consider any alternative candidate network in which senders are connected to intermediaries i_1 and i_2. If there is any intermediary link that is not used by i_1 or i_2 along the set of flexible paths, then it is ruled out as an equilibrium network. Regarding necessary conditions, manipulating a candy equilibrium network structure can sometimes yield a non-candy equilibrium

tor-periphery network. The manipulation involves merging two isomorphic candy structures, a candy with relays i_1 and j, and a candy with relays i_2 and j, in a way that i_1 is used on paths between i_2 and j and using i_2 is used on paths between i_1 and j. For example, consider $m = 1, 2, 3$. The candy between two relays needs 5 links to provide flexibility. Now think of two sender relays a, b and one receiver relays c, and one non-relay intermediary d. Form all links except (c, d). In this structure, there are 5 links, both (a, c) and (b, c) have flexibility, and the structure is not a candy. Although the combinatorial problem makes a formal proof intractable, this demonstrate that a tor-periphery structure achieves flexibility with an efficient number of links.

We view ϵ-equilibrium as more suitable solution concept from a **positive** standpoint. First, note that the candy tor-periphery economizes on link costs between intermediaries, and achieves this by reducing the number of potential connections required to link all senders and receivers through the sender and receiver relays. Intuitively, for a large number of agents, the cost savings associated with reducing links between intermediaries becomes relatively small. However, this is also not a "robust" outcome. Consider a small perturbation to the model, in which pair-wise link costs have small heterogeneity. In a large economy with sufficiently many senders and receivers, in the margin, each sender/receivers would be choose an intermediary with the lowest link cost. With this, the candy tor-periphery does not hold. We conjecture that, in the discrete case, if

1. For each $a, b \in A$, the cost of the link between a and b is $c + \epsilon_{ab}$ where $\epsilon_{ab} \sim F$ is a small enough i.i.d. error term,

2. The cost of links are additive,

3. Keeping the number of intermediaries fixed, if the number of senders and the number of receivers are large enough,

then all equilibrium networks take a tor-periphery shape, as described in the paper.

D Trails and Other Transmission Paths

In this section, we provide more detail on the transmission path strategies, and in particular, why loop-like transmissions are not desirable from the agents' perspectives. Recall that m_s corresponds to the number of intermediaries on a path. For example,

if the path used is

$$(\text{sender}, \text{intermediary}_1, \text{intermediary}_2, \text{receiver})$$

then $m_s = 2$ unravels the path and the regulator wins. Next notice that we have assumed $\underline{m} \geq 1$ and $\kappa(\underline{m}) = 0$. This means, it is always free for the regulator to investigate paths with a single intermediary. For this reason, the insiders never use a path with a single intermediary such as

$$(\text{sender}, \text{intermediary}_1, \text{receiver})$$

Using such a path would mean probability 1 of getting caught.

Given that all transmission paths have at least two intermediaries, there is no reason to connect a sender and a receiver to the same intermediary.

The second step is to observe that loops are never used by the insiders. The way we think about the loops and the search is as follows.

Suppose insiders use a trail with a loop:

$$(\text{sender}, \text{int}_a, \text{int}_b, \text{int}_c, \text{int}_d, \text{int}_b, \text{receiver})$$

The search goes as follows:

1. Regulator observes that receiver made abnormal gains by trading on the sender's company.

2. Regulator searches the receiver, identifies that int_b sent info (about the sender's company) to the receiver.

3. Regulator searches int_b, identifies identifies that both int_d and int_a sent info to int_b.

   (a) Regulator searches int_d and identifies that int_c sent info to int_d (about the sender's company)

   (b) Regulator searches int_a and identifies that *sender itself* sent info to int_a (about the sender's company)

4. Search concludes by unraveling

$$(\text{sender}, \text{int}_a, \text{int}_b, \text{receiver})$$

Therefore, if $m_s \geq 2$, the regulator wins. The regulator does not need to match the length of the trail, but only the shortest path in the trail.

Therefore, for the insiders, using a trail such as

$$(\text{sender}, \text{int}_a, \text{int}_b, \text{int}_c, \text{int}_d, \text{int}_b, \text{receiver})$$

is weakly dominated by using the shortest path inside the trail

$$(\text{sender}, \text{int}_a, \text{int}_b, \text{receiver})$$

since longer paths lead to losses in value (β is strictly decreasing). Using int_c and int_d is redundant loss in value for the insiders.

Together this implies that loops are never used, and paths with a single intermediary is also not used. We observe that it would tie the hands of the insiders to connect (a positive mass of) senders and receivers to the same intermediary. Sender-receiver pairs who are connected through a single intermediary can never transmit info between each other. This leads to the endogenous separation between sender relays and receiver relays.

E Proofs

Proof of Theorem 1

Consider choosing m. If A sends with Δ, then A gets $u_A = \beta(\Delta) - \iota_{m \geq \Delta}\gamma(\Delta)$ and G gets $u_G = -\kappa(m) + \iota_{m \geq \Delta}\gamma'(\Delta) - \beta'(\Delta)$. If A does not send, A gets 0 and G gets $-\kappa(m)$. G never plays $m < \underline{m}$ as $\underline{m}$ is free. In fact we assumed $m < \underline{m}$ away from the action set. G never plays $\overline{m} + 1$ or more, because $\overline{m}$ strictly dominates these.

Let the set of available path lengths between $\underline{m} + 1$ and $\overline{\Delta}$ be D, and enumerate its elements $\Delta_1 < \Delta_2 < ... < \Delta_{|D|} = \overline{\Delta}$. Denote $\underline{m} = \Delta_0$.

Consider an equilibrium. Note the two lemmas:

(a) For any k between 0 and $|D| - 1$, if $m = \Delta_k$ has 0 probability, then $\Delta = \Delta_{k+1}$ has 0 probability because A would shift the probability down to increase benefits without reducing the cost.

(b) For any k between 1 and $|D| - 1$, if $\Delta = \Delta_k$ has 0 probability, then $m = \Delta_k$ has 0 probability because G would shift the probability down to reduce costs without reducing benefit.

(c) By induction using (a) and (b), $m = \Delta_0$ has positive probability.

(d) $\Delta = \Delta_{|D|}$ guarantees positive u_A. So not sending has 0 probability. Then $m = \underline{m}$ gives $u_G = -\beta'$.

(e) If $\Delta = \Delta_{|D|}$ has 0 probability, then $m = \Delta_{|D|-1}$ gives $u_G > -\beta'$.

By (c),(d),(e), $\Delta = \Delta_{|D|}$ has positive probability. Then by (a), (b), and induction,

all $m = \Delta_0$ to $\Delta_{|D|-1}$ and all $\Delta = \Delta_1$ to $\Delta_{|D|}$ have positive probability. A puts positive probability on $\Delta = \Delta_{|D|}$ which is larger than all m. So by indifference conditions, $u_A = \beta(\Delta_{|D|}) = \beta(\overline{\Delta})$ and $u_G = -\beta'$.

Proof of Theorem 2 A tor-periphery offers all distances from $\underline{m}+1$ to $\overline{m}+1$ for every $s-r$ pair. Along the lines of Theorem 1, (σ_p^*, σ_m^*) is characterized by the A's indifference between $\underline{m}+1$ to $\overline{m}+1$ and G's indifference between $\underline{m}$ to $\overline{m}$. This yields 0 payoff to G and $\beta(\overline{m}+1)$ interim payoff to A because A puts positive probability on $\overline{m}+1$ and G cannot match $\overline{m}+1$. Then

$$V_A(L^*, \sigma_p^*, \sigma_m^*) = \zeta|S|\beta(\overline{m}+1) - \eta\left(|S|+|R|\right) - c(T)$$

The only task is prove that $V_A(L^*, \sigma_p^*, \sigma_m^*) \geq V_A(L, p, \sigma_m^*) - \epsilon|A|$ condition holds.

Take any L. Conditional on a pair, regardless of distances available in L, the highest payoff with any p against σ_m^* is $\beta(\overline{m}+1)$. This follows from the fact that σ_p^* is a best response against σ_m^* when all rationalizable path distances are available to pick.

Let S' and R' be the non-isolated senders and receivers. Others cannot take part in transmission. Take any $n_{k,\epsilon}^* > \frac{\eta'}{4\epsilon}k^2$. Then

$$\begin{aligned}
V_A(L, p, \sigma_m^*) &\leq \zeta|S'|\frac{|R'|}{|R|}\beta(\overline{m}+1) - c(L) \\
&\leq \zeta|S'|\frac{|R'|}{|R|}\beta(\overline{m}+1) - \eta\left(|S'|+|R'|\right) \\
&\leq \zeta|S|\frac{|R|}{|R|}\beta(\overline{m}+1) - \eta\left(|S|+|R|\right) \\
&= V_A(L^*, \sigma_p^*, \sigma_m^*) + c(T) \\
&< V_A(L^*, \sigma_p^*, \sigma_m^*) + \eta'\frac{1}{2}|T|^2 \\
&< V_A(L^*, \sigma_p^*, \sigma_m^*) + \epsilon|A|
\end{aligned}$$

Proof of Theorem 3 We can follow the logic in the proof of the discrete case for sufficiency. Consider any tor-periphery network L^*. Along the lines of Theorem 1, (σ_p^*, σ_m^*) is characterized by A's indifference between $\underline{m}+1$ to $\overline{m}+1$ and G's indifference between $\underline{m}$ to $\overline{m}$ (for almost every pair in Lebesgue measure, not every pair). This yields 0 payoff to G and $\beta(\overline{m}+1)$ payoff to A. Then

$$V_A(L^*, \sigma_p^*, \sigma_m^*) = V^* := \zeta\mu_S\beta(\overline{m}+1) - \eta\left(\mu_S+\mu_R\right)$$

Take any L and p. Conditional on a pair, regardless of distances available in L, the highest payoff with any p against σ_m^* is $\beta(\overline{m}+1)$. This follows from the fact that σ_p^* is a best response against σ_m^* when all rationalizable path distances are available to pick.

Let μ_S' and μ_R' be the non-isolated senders and receivers. Others cannot take part in transmission. Then

$$\begin{aligned} V_A(L,p,\sigma_m^*) &\leq \zeta\mu_S\frac{\mu_R'}{\mu_R}\beta(\overline{m}+1)-c(L) \\ &\leq \zeta\mu_S\frac{\mu_R'}{\mu_R}\beta(\overline{m}+1)-\eta\left(\mu_S'+\mu_R'\right)=V^* \end{aligned}$$

So all tor-periphery networks are equilibrium networks.

For necessity, notice that A can always deviate to forming a tor-periphery and choosing $\overline{m}+1$ path-distance at each pair. This yields V^* payoff with certainty since G cannot win against $\overline{m}+1$. So A gets at least V^* payoff in any equilibrium.

Consider any equilibrium (L',σ_p',σ_m'). The conditional interim payoff of A on (s,r_s) such that (s,r_s) does not have a path of distance at least $\overline{m}+1$ is 0 since A needs to mix with not sending information. For the remaining (s,r_s), the conditional interim payoff is $\beta\left(\overline{\Delta}(s,r_s,L)\right)$. Thus

$$\begin{aligned} V_A(L',\sigma_p',\sigma_m') &\leq \zeta\mu_S\frac{\mu_R'}{\mu_R}\beta(\overline{m}+1)-c(L) \\ &\leq \zeta\mu_S\frac{\mu_R'}{\mu_R}\beta(\overline{m}+1)-\eta\left(\mu_S'+\mu_R'\right)=V^* \end{aligned}$$

So in any equilibrium A has at most V^*. Therefore, in any equilibrium A has exactly V^* payoff. So the equality in $V_A(L',\sigma_p',\sigma_m')\leq V^*$ holds. The equalities in all previous inequalities hold only if and only if (i) $\mu_S=\mu_S'$, $\mu_R=\mu_R'$, (ii) for a.e. (s,r_s), there exists a path of distance $\overline{m}+1$ between s and r_s, (iii) $c(L')=\eta\left(\mu_S+\mu_R\right)$. These make up a necessary condition for equilibrium.

There is one more necessary condition. Notice that L^* also costs V^*. So A can deviate from its transmission strategy to any other transmission strategy by doubly deviating to L^*. So the best response cycle and the proof of Theorem 1 applies. A must have positive probability on all path lengths $\underline{m}+1$ to $\overline{m}+1$ for almost every (s,r) pair. This yields the additional necessary condition: (iv) between almost every pair (s,r) there are paths of all distances $\underline{m}+1$ to $\overline{m}+1$ in L.

The final step is to show that (i), (ii), (iii), (iv) necessitate tor-periphery networks. Recall that each link must have at least one intermediary by assumption. So $A\backslash I$

cannot have links among each other. Also I is finite. So $c(L)$ accrues solely from links in $I \times (A \backslash I)$. By (iii)

$$\sum_{i \in I} \mu_i = \frac{c(L')}{\eta} = \mu_S + \mu_R$$

Then by finiteness of I and (i), almost every I has has exactly one link.

Consider an intermediary i s.t. $\mu_i > 0$. If i is linked to a positive measure of senders and positive measure receivers, almost every one who is linked only to i, then these pairs of senders and receivers immediately get caught when they transmit information (because $\underline{m} \geq 1$). So either i's a.e. linked agents are senders or i's a.e. linked agents are receivers. Depending on which, assign i either as a sender relay or receiver relay. Assign the remaining intermediaries as middle relays. By (iv), a.e. sender relay-receiver relay pair must be connected with paths of distance $\underline{m} - 1, ..., \overline{m} - 1$. This concludes the proof that L' is a tor-periphery, with $T \subset I$.

Proof of Theorem 4 The proof is identical to the sufficiency part of the proof of Theorem 3.

Proof of Theorem 5 Transmission to f_s yields expected utility $\beta(0) - \delta\gamma(0)$ to (s, f_s). Denote μ'_s the equilibrium mass of senders who choose the insider network over their social network. Then the expected payoff to (s, f_s) from joining the insider network is $\Phi(\mu'_s) \equiv \max\left\{\zeta\beta\left(\overline{m}+1\right)\frac{\mu'_S}{\mu'_S+\mu_R} - \eta, 0\right\}$. Note that Φ is increasing. ($\Phi(\mu'_s)$ can be 0 because the insiders do not form any links if two few senders join insiders and the expected transmission payoff does not cover link costs.)

Consider $\delta^* \equiv \frac{1}{\gamma(0)}\left(\beta(0) - \left(\zeta\beta\left(\overline{m}+1\right)\frac{\mu_S}{\mu_S+\mu_R} - \eta\right)\right)$. Note $\delta > \delta^* \iff \Phi(\mu_s) > \beta(0) - \delta\gamma(0)$. If $\delta > \delta^*$, since Φ is increasing, the highest possible payoff for any sender is obtained when all senders join the insider network. So the unique efficient equilibrium is given by $\mu_S = \mu_{S'}$. If $\delta < \delta^*$, then $\beta(0) - \delta\gamma(0) > \Phi(\mu_S) \geq \Phi(\mu'_S)$ so that using social networks yields a higher payoffs than the insider network for any number of senders μ'_s who might join the insider network. So the unique efficient equilibrium is given by $\mu'_S = 0$.

Note that when $\Phi(0) < \beta(0) - \delta\gamma(0) < \Phi(\mu_S)$, there are inefficient equilibria with $\mu'_S = 0$ due to coordination failures at the stage when each sender is choosing between tge social network and the insider network.
